"Experimental neurosis." When an animal is presented with a problem which requires a fine degree of differentiating ability, i.e., when a conflict between inhibitory and excitatory processes is set up, either inhibition or excitation may gain the upper hand with the suppression of the opposite process. In the former event the animal may become drowsy and fall into a deep sleep (p. 919), whereas in the latter a nervous disturbance develops during which even gross differentiation cannot be accomplished. To give an example, a dog was required to discriminate between two visual stimuli, a circle and an oval, the former being followed by feeding (positive stimulus), while the latter was not reinforced (negative stimulus). Differentiation was made more and more difficult by making the oval at each successive trial more nearly circular. The experiment proceeded smoothly until the axes of the two figures had a ratio of 8:9. The animal then became fractious, howled and whined in its cage, struggled with its harness and became incapable of discriminating between any oval shape and a circle. Not until after a prolonged rest was the animal's power of discrimination between the two shapes restored, but upon being then confronted with the same problem the nervous disorder returned. *"Experimental neurosis,"* as this state was termed by Pavlov, has also been induced in sheep and pigs by Anderson and Liddell. In some instances the condition was permanent, and Gantt has reported such a state which has persisted for upwards of four years. The neurosis in this latter instance developed as a result of a conflict aroused in the differentiation of two auditory conditioned stimuli—two closely similar tones. These interesting observations upon experimental neuroses give an insight into brain physiology. They have important psychiatric implications and may give a lead in the interpretation of certain nervous conditions in the human subject (see p. 891.)

Synthesis of stimuli

The development of the conditioned response is, in itself, evidence of the synthesizing or associative ability of the cortex. Further evidence is afforded by experiments with compound stimuli, i.e., the fusion of separate individual stimuli, whether these act upon the same or upon different analyzers, into a conditioned complex.

As an example of simultaneous stimuli acting

upon the same analyzer,—an alimentary conditioned reflex was established to a chord of three tones of equal intensity but of 85,256 and 786 c.p.s., respectively. Later each tone when sounded separately caused a response. The responses to the different tones were approximately equal but weaker than that caused by the chord.

A conditioned reflex may be established to a compound stimulus made up of two stimuli acting *simultaneously* but upon different analyzers. If the component stimuli are then applied separately and without reinforcement, it is found that one of the pair is effective but not the other. For example, a conditioned reflex to acid was established to a compound stimulus consisting of the simultaneous application of a tactile stimulus and a thermal stimulus of 0°C. The tactile stimulus when applied alone was found to be about as effective as the compound stimulus, whereas the thermal stimulus was quite ineffective. The results of experiments in which the component stimuli of the compound stimulus were of unequal strengths, and applied to the same analyzer, indicate that the factor determining the effectiveness of the stimuli, when applied separately, is their relative intensity. The thermal stimulus used in the foregoing experiment may therefore be regarded as being the weaker of the two stimuli. Visual stimuli are also weaker than those acting upon the auditory analyzer. For example, after a conditioned reflex had been established to a compound stimulus made up of a tone and a light, the tone by itself caused a response, whereas the visual stimulus was quite ineffective. However, the weaker stimulus undoubtedly plays its part in the combination, for if the stronger component is applied repeatedly without reinforcement by the unconditioned stimulus, but the compound stimulus is constantly reinforced, the stronger stimulus by itself becomes ineffective, whereas the compound stimulus retains its full effect.

The cortex is also able to synthesize *successive* stimuli into a compound conditioned stimulus. For instance, a flash of light (L), a cutaneous stimulus (C) and the sound of bubbling water (S) when applied in the order (L—C—S) were compounded into a positive conditioned stimulus. The reverse order (S—C—L) after differentiation (by non-reinforcement) was entirely without effect.

Similarly, four tones having vibration frequencies of 290, 325, 370 and 413 c.p.s. respectively when sounded in this order (1, 2, 3, 4) were successfully differentiated by a dog from all other

sequences (e.g., 4, 3, 2, 1; 4, 3, 1, 2; 4, 1, 3, 2; 4, 2, 3, 1, etc., etc.).

The series of sounds in a word (e.g., a dog's name) or in a command is a familiar example of a successive compound conditioned stimulus.

Irradiation and concentration

These features are best illustrated by citing an actual experiment. The skin of the hind limb was stimulated at 5 separate places. One of these situated upon the paw was differentiated by non-reinforcement in the usual way from the other four. That is, the place upon the paw was given inhibitory properties (p. 911). The other four places, which through reinforcement were given positive conditioned properties, were placed at progressively further distances along the limb from the inhibitory place. It was found that if the latter was stimulated three times in succession, and one minute after the last stimulation, the positive place nearest the inhibitory place was then stimulated, there was complete failure of the usual conditioned response. Stimulation of the next (second) excitatory place one minute after the last application of the inhibitory stimulus was followed by a response half as great as usual. The remaining two places (third and fourth) gave a normal or somewhat greater than normal response (see positive induction, p. 914). When the number of the previous stimulations of the inhibitory place was increased, and the interval following the last one shortened to $\frac{1}{4}$ minute, all four excitatory places gave a reduced response. As time elapsed the furthest place was first freed from the inhibitory influence, and the others in the order of their positions from the inhibitory place. The point nearest to the latter in some cases did not give a full response until the lapse of 10 minutes after the application of the last stimulus to the inhibitory place. It can also be shown that if, by means of extinction, inhibitory properties are given to one of the four excitatory places the inhibitory process spreads to involve the others.

These results are taken to indicate that each stimulated area has its circumscribed representation in the cortex. Inhibition initiated in the cortical cells to which the inhibitory place is projected *irradiates* to involve the cortical projection areas of the positive places. The gradual release of the cortical areas from the inhibitory influence, and its retreat to the original cortical cells corresponding to the inhibitory place is called the *concentration of inhibition*. Irradiation and concentration are antagonistic processes. These

processes can also be shown for the acoustic analyzer and they most probably exist for other analyzers as well. The following is an illustration of irradiation within the acoustic analyzer. Positive conditioned reflexes were established respectively to the beat of a metronome, to a musical tone and to a buzzing sound. When the reflex to the buzzing sound or to the metronome was extinguished the inhibitory process spread to involve the reflex to the musical tone.

Irradiation is not confined to the analyzer in which the inhibitory process originates. It can be shown that the inhibitory process initiated in one analyzer spreads to others and may involve the entire cortex. For example, a positive alimentary conditioned reflex was established to a tone of 4000 c.p.s.; a note a semitone lower than this was given inhibitory properties by differentiation. When the inhibitory stimulus was applied a short time before a visual conditioned stimulus,

ties of a stimulus developed by means of differentiation can be readily destroyed again (disinhibited) by repeated reinforcement. If, however, application of the inhibitory stimulus is preceded by a positive one and both are reinforced the inhibitory properties of the former are strengthened and can be abolished only after a great number of trials. Thus, a metronome beating at a rate of 60 beats per minute served as a positive conditioned stimulus and a rate of 120 beats per minute as a differentiated (differential inhibition, p. 81). The inhibition was then almost abolished by reinforcement but was reestablished again when the differentiated stimulus (rate of 120 beats per minute) was preceded by the positive stimulus (rate of 60 beats per minute). The results are shown in table 81, given by Pavlov.

POSITIVE INDUCTION in its simplest form may be illustrated as follows. A positive conditioned reflex was established to stimulation of the foot of the hind paw. A stimulus to the hind paw was given inhibitory properties by differentiation. When the excitatory place (forepaw) was stimulated immediately after the application of the stimulus to the inhibitory place, the positive conditioned reflex was enhanced (salivary secretion increased by 50 per cent). The excitability of the cortical area receiving impulses from the forepaw had evidently been increased as a result of inhibition of the cortical area corresponding to the hind paw. The excitability of the cortex in proximity to the inhibited area is enhanced for the moment but then becomes depressed as a result of the irradiation of the inhibitory process. When dealing with irradiation it was pointed out that the inhibitory effect was demonstrable for several seconds after the application of the inhibitory stimulus. Pavlov holds the view that these two processes, positive induction and irradiation of inhibition (or negative induction and the irradiation of excitation), are constantly interacting with one another and spread wave-like over the cortex. Positive induction precedes, respectively negative induction, spread of the inhibitory or excitatory process.

THE EMPLOYMENT OF CONDITIONED REFLEXES IN THE STUDY OF CORTICAL FUNCTION. Information concerning the localization of functions in the cortex was obtained by, first, firmly establishing a conditioned reflex involving one or other analyzer, then excising a certain portion of the cortex and studying the effects of the operation on the conditioned response.

TABLE 81

TIME	CONDITIONED STIMULUS APPLIED DURING 30 SECONDS	SALIVARY SECRETION IN DOGS DURING 30 SECONDS
11.25 a.m.	60 beats	0
11.30 a.m.	60 beats	0
11.42 a.m.	60 beats	3
11.49 a.m.	60 beats	4
11.56 a.m.	120 beats	8½
12.06 p.m.	60 beats	0

All the stimuli were accompanied by reinforcement

the reflex which had been established to the latter, as well as that established for the positive auditory stimulus, (tone of 4000 c.p.s.) was inhibited.

Irradiation and concentration of excitation occur in a manner analogous to that described for inhibition. Generalization (p. 911) is ascribed to the irradiation of excitation from the primary cortical focus. Differential inhibition, on the other hand, antagonizes the excitory process and concentrates it within the original cortical area.

Induction

Induction is a feature of conditioned reflex action analogous to the phenomenon of the same name described as occurring in spinal reflexes (p. 813), namely, the increase of inhibition caused by a preceding state of excitation (*negative induction*) or an increase of excitation caused by a previous state of inhibition (*positive induction*). Induction is therefore a reciprocal process.

NEGATIVE INDUCTION. The inhibitory proper-

Removal of the entire cortex

The dog removal of the entire cortex results in complete and permanent loss of all conditioned responses, natural or artificial; new conditioned reflexes cannot be established. The decorticated animal responds to crude unconditioned stimuli, e.g., a bright light or sound, its responses being frequently those of resentment or rage (p. 884). The unconditioned salivary reflex is at first but eventually becomes stronger than normal.

Removal of a limited portion of the cortex

Removal of a limited portion of the cortex, e.g., temporal or occipital lobes, causes the disappearance for a time of all "artificial" conditioned reflexes, and sometimes of the "natural" ones as well. Unconditioned reflexes, which are dependent upon subcortical centers, remain in abeyance for a few hours or may not disappear at all. The recovery of conditioned reflexes depends upon analyzers, other than the one which has been directly injured, occurs after a few days, and is nearest to the excised area recovering later than those farther removed. The positive conditioned reflexes when they return are frequently of the normal strength. Inhibitory processes, on the other hand, much weaker than normal, take a longer time. Incomplete recovery of the injured cortex or eventually takes place. After scar tissue has formed convulsions frequently occur, being preceded by a complete disappearance of conditioned responses.

THE ACOUSTIC ANALYZER is centered in the temporal lobe. Extirpation of both temporal lobes is followed by a very temporary loss, if any, of auditory unconditioned reflexes (e.g., pricking the ears to sound). The auditory conditioned reflexes may not return for several weeks or months, and are never fully restored. The more discriminating reactions are particularly lost. Discrimination (p. 911) of the frequency, pitch and quality of sound is possible, but the powers for more complicated analyses and syntheses are not regained. The animal, for example, never answers to its name, and the discrimination of other types of compound auditory stimuli (p. 913), e.g., a descending from an ascending scale of tones, cannot be established.

An experiment upon the peripheral portion of the auditory analyzer may be mentioned here, since it has a bearing upon Helmholtz' theory of hearing. Destruction of the organ of Corti in the upper part of the cochlea (sensitive for lower tones) resulted in a loss of condi-

THE VISUAL ANALYZER is situated mainly but not exclusively in the occipital lobe. According to Pavlov the visual analyzer is probably spread over the entire cortex. Complete bilateral extirpation of the occipital lobes causes effects upon the visual conditioned reflexes corresponding to those upon the auditory reflexes which follow removal of the temporal lobes. Conditioned responses to changes in the intensity of illumination (e.g., switching on a high power lamp) established before operation returned upon the fifth day following the extirpation of the occipital lobes as well as of a considerable area of the cortex lying anterior to them. Differentiation was established between a luminous cross and a circle illuminated to the same intensity. It was found impossible, however, to establish conditioned reflexes to specific objects. The explanation for this probably is that the appearance of an object changes with the illumination, with its distance from the eye and the angle from which it is observed. Its recognition under different conditions of lighting, position, etc., therefore requires a much greater power of analysis and synthesis than that required for the differentiation of a flat luminous shape. The animal deprived of its occipital lobes is able, nevertheless, to avoid objects placed in its path. They are detected simply by the changes in illumination (lights and shadows) which their presence creates.

The findings described above, namely, that complete decortication in the dog abolishes all conditioned reflexes, and that removal of the temporal or occipital lobes impairs, respectively, auditory, and visual conditioned reflexes, but does not destroy them permanently and completely, lead to the following conclusions concerning the functions of the cortex, so far at any rate as the auditory and visual senses are concerned. (a) Though rudimentary reactions can be carried out through subcortical connections, the processes underlying conditioned reflexes are dependent upon the activity of the cerebral cortex. (b) The highest powers of analysis and synthesis are localized to definite areas, each of which may be regarded as the "nucleus" of a given analyzer. (c) The analyzer, however, is not rigidly confined to this area but extends into other cortical regions in which less complicated types of analysis can be

tioned reflexes which had been established to tones of the lower part of the musical scale (frequencies lower than 600 d.v. per minute). Reflexes to higher tones were unaffected.

undertaken. Experiments involving other analysers have yielded evidence pointing in the same direction:

These results of cortical extirpation cannot be directly applied to the human subject since the functions of subcortical centers of hearing, sight, etc., in lower animals have not, as in man, been entirely usurped by the cortex. Nevertheless, Pavlov's observations are, broadly speaking, in harmony with modern conceptions of cortical functions (see p. 891). A given sensory function, though primarily "centered" in a certain cortical area, is dependent for its full development upon other areas as well.

THE EFFECTS OF DRUGS UPON CONDITIONED REFLEXES

Caffeine and *strychnine* increase the effects of positive conditioned stimuli and weaken internal inhibition. After a dose of less than 1 grain (0.025 to 0.05 gram) of the former drug, extinction (inhibition) of a conditioned reflex is effected with the greatest difficulty. *Bromides* act by strengthening internal inhibition, and not by directly depressing excitatory processes; under their influence the extinction of positive conditioned reflexes is facilitated. *Alcohol* in moderate doses weakens internal inhibition. Recently Andreyev and Pugsley have found that the *hypercalcaemia* resulting from parathormone or ergosterol overdosage causes an exaggeration of inhibitory processes, the after effect of inhibitory stimuli is enhanced and extinction of positive conditioned reflexes accelerated. The inhibitory effect of the hypercalcaemia is antagonized by caffeine.

THE PHYSIOLOGY OF SLEEP

THE DEPTH OF SLEEP

The depth of sleep is not constant throughout the sleeping period but varies from hour to hour. Experiments upon man in which auditory stimuli were employed to arouse the subject at different times, or the movements of the sleeper were recorded (the depth of sleep being assumed to be inversely related to the amount of muscular movement) indicate that the depth of sleep follows a characteristic curve. In most adults sleep deepens rapidly to the end of the first hour, after which it lessens sharply for a time, and then more slowly till the time of waking. In children the sleep curve shows two maxima, i.e., two periods of the deepest sleep, one of these is reached in the first or second hour, the other between the eighth and ninth hours; the curve then falls rapidly to the time of waking. Generally speaking, sleep taken

during the daytime is lighter than that at night. Deep sleep is dreamless, dreamless only during light sleep and chiefly in the which just precedes waking. In sleep consciousness is not uniform for all senses, that of sleep is greatest for the sensations and least for those of pain, hearing and

The sleep requirement of different persons widely; it also varies with age. The following average figures for the amount of sleep at different periods of life.

New-born infant	18
Growing children	12
Adults	8
Old persons	5

PHYSIOLOGICAL CHANGES ACCOMPANYING

During sleep most bodily functions are to their basal levels. The blood pressure is the systolic pressure showing a decline of to 30 mm.Hg. The lowest level is reached the fourth hour of sleep; this level is maintained until a short time before awakening, after which pressure commences to rise again. Maschke found that if the sleep was disturbed by dreams the blood pressure might be well above the normal waking level, e.g. 130 mm.Hg., up to 180 or even 200 mm.Hg. pulse rate is slowed by from 10 to 30 beats per minute, the metabolic rate is reduced by from 10 to 15% below the basal level and the rectal temperature by a fraction of a degree Fahrenheit. The regulating mechanisms are depressed: respirations are slowed as a rule, and also become more costal in character; they also become irregular or periodic. Muscular activity is minimal, the knee jerk is abolished, and Babinski may be present. The three most somatic reflexes are definitely raised: motor reflexes, however, are more or less present. In most animals the righting reflexes are retained. The pupils are usually constricted; the reflex is retained. The eyeballs are turned inward and outward. Urine volume is reduced, absolute excretion of urinary phosphate is increased, and the specific gravity ratio of the sweat glands is not increased; according to Hartnagel the amount of fluid lost per hour in sleep is nearly equal to that lost during a corresponding period of muscular exercise. Gastric secretion is or little altered during sleep. The con-

stomach continue and may be more usual; the rate of digestion is about normal during the waking state. *Lacrymal* secretions are reduced.

THEORIES OF SLEEP

and nature of sleep have aroused om the time of the Greek philosophers t day, but though hypotheses are ten ill-founded, facts which might upon the underlying processes are alt to obtain. A discussion of only more important theories, will be

THEORY (Lépine, Duval). This theory e demonstration by Cajal that there omical continuity between adjacent erely points of contact, for which the was later suggested by Foster. The ostulated that the function of the cells rtical centers was suspended as a result

of the retraction of the dendritic processes, and the consequent break in contact between neurones. Though some histological evidence was cited in support of this conception, the theory was mainly speculative.

(2) CEREBRAL ISCHEMIA THEORY. Howell suggested that fatigue of the vasomotor center with consequent vasodilatation of the peripheral vessels, especially of the skin, and reduction in cerebral blood flow was the primary change responsible for the onset of sleep. The flushed skin of the sleeping subject, the fall in blood pressure and the well-known feeling of drowsiness following a meal (which presumably was the result of the diversion of blood to the splanchnic area) lent plausibility to the theory. From ancient times the carotid artery (Karoō = I sleep) has been believed to be connected in some way with the mechanism of sleep, for it was recognized that compression of this vessel was not uncommonly followed by unconsciousness. In later times the loss of consciousness following pressure upon the neck was attributed to vagal stimulation, with consequent inhibition of the heart and a reduction in intracranial blood flow. We know now that the unconsciousness is due to the fall in blood pressure brought about through the carotid sinus mechanism.

The unconscious states caused by a reduction in cerebral blood flow are not, however, akin to normal sleep. Vulpian observed some years ago that, though stimulation of the cervical sympathetic in animals caused cerebral ischemia, sleep was not induced. Moreover, Gibbs has recently shown by means of an electrically heated stylet inserted into the jugular vein of human subjects (p. 291) that no diminution in blood flow through the brain occurs during natural sleep. It is possible, nevertheless, that there may occur a reduction in the blood supply to a limited area of the brain whose activity is essential for the waking state. A limited vascular change of this nature might not be revealed by observations upon the total intracranial blood flow. With regard to the carotid sinus and its possible relationship to the sleep mechanism, a recent interesting observation should be mentioned. Weiss and his associates describe states resembling normal sleep as resulting from pressure upon the sinus in certain susceptible subjects. The notable feature of this reaction is that unconsciousness is not accompanied by a significant change in heart rate, blood pressure or in the blood flow through the brain. In some instances there was actually a rise in blood pressure preceding and during the unconscious state. The

effect of carotid sinus stimulation in these instances appears to have a purely nervous basis, the sensory part of the mechanism being the sinus nerve and the receptors in the sinus wall. The brain center or centers involved are unknown. Koch also reported in 1932 that in dogs recovering from anesthesia, stimulation of the carotid sinus caused the immediate cessation of muscular movement, the head and tail of the animal gradually hung more and more limply, or as Koch expresses it, "The animal sinks loosely together, often on its side, to be as in sleep."

(3) **CHEMICAL THEORIES.** Several chemical theories of sleep have been proposed. One of the earliest of these was that fatigue products, especially lactic acid, formed in the tissues generally, acted by depressing the function of the cortex. Against this view is the well-known fact that one need not be fatigued in order to sleep; on the other hand, a person may be unable to sleep though utterly fatigued. Furthermore, the brain tissue actually derives energy from the oxidation of lactic acid.

A more recent chemical theory is that of Pieron. This observer claims that a substance, which he terms *hypnotoxin*, is produced by the brain tissue and acts as a soporific. He claims that the cerebrospinal fluid of a dog killed during sleep induces sleep when injected into another animal. Kroll makes similar claims, stating that an acetone extract of the brain of a sleeping or hibernating animal will cause sleep when injected into another. Holmes has been unable to confirm Kroll's findings. An extract prepared by Kroll's method either from sleeping or waking animals was found to be lethal through its toxic effect upon the heart. Ivy and Schnedorf have repeated Pieron's experiments and confirmed his observation. They found that the injection of cerebrospinal fluid of a dog kept awake for several days induced a state of depression resembling deep sleep in rested dogs, when introduced into the cisterna magna or cerebral ventricle. The effect, however, is probably due, not to the presence of a sleep-inducing substance in the "fatigued" cerebrospinal fluid, but to a rise in intracranial pressure, since the injection of cerebrospinal fluid from rested dogs had a depressing action not considerably less than that of the "fatigued" fluid. No evidence in support of the theory (Dikshit) that *acetylcholine* liberation by the brain tissue is a factor in sleep was secured by these observers.

Zondek and Bier have advanced an interesting theory in which the pituitary plays a leading rôle. They state that the pituitary during the waking state has a higher concentration in bromine than any other tissue but that during sleep the bromide concentration of the gland diminishes while that of the medulla increases. These observers therefore believe that sleep is induced through the liberation of a bromine

compound from the hypophysis. They have named this substance *bromhormone*. The evidence upon which this theory is based is far from convincing.

(4) **THE HYPOTHALAMUS AND SLEEP.** Several observations both clinical and experimental point to the existence of a sleep center in the diencephalon. Hypersomnolence is a frequent accompaniment of tumors of the structures in the floor and walls of the third ventricle, or of inflammatory lesions involving the hypothalamic region. Hess claims to be able to cause sleep in animals by mild electrical stimulation of the diencephalon towards the anterior end of the cerebral aqueduct. He has also reported that ergotamine injected directly into the third ventricle induces sleep. Ergotamine paralyzes the motor and secretory fibers of the sympathetic. Since the parasympathetic and sympathetic centers are apparently situated in the hypothalamus, Hess argued that the drug by suspending the activity of the sympathetic center caused a preponderance of parasympathetic effects. Sleep, he concluded, was a parasympathetic function. He also draws support for his theory from certain manifestations of parasympathetic activity, namely, the pupillary constriction, bradycardia and vasodilatation which accompany sleep. Though this observer's idea that sleep is a parasympathetic function requires further experimental support before it can be accepted, the evidence for the participation of the hypothalamus in the sleep mechanism is very strong. Yet, contrary to the idea that sleep is caused by excitation of some part of the hypothalamus, other investigators believe that it results from the *depression* of hypothalamic activity. The hypothalamus is thus regarded as containing a waking center, sleep following its inhibition. Ranson and his associates, for example, have reported that sleep can be readily induced in cats by lesions confined to the mammillary bodies, but that it did not result from the stimulation of any part of the hypothalamus. Harrison also found that electrical stimulation of the hypothalamus caused somnolence only when the current exerted a destructive action.

(5) **PAVLOV'S THEORY.** Pavlov believes sleep and internal inhibition to be essentially one and the same process, i.e., sleep is simply the spreading (irradiation) of internal inhibition over the entire cortex with the subsequent involvement of subcortical levels; and internal inhibition confined within the boundaries of a single analyzer is a localized sleep. He was led to this conclusion by

the behavior of animals during his investigations of conditioned reflex action. Drowsiness and sleep were frequent accompaniments of all forms of internal inhibition, e.g., inhibition of extinction and of delay (p. 910), conditioned and differential inhibition, or the inhibition which ensued spontaneously after the repetition of positive conditioned reflexes over a long period of time. An animal, for example, which is quite alert during the establishment of a reflex to a definite musical tone becomes drowsy and falls asleep in the stand during attempts to develop differentiation (p. 911) of a closely similar tone; its muscles relax, it may snore loudly and other positive conditioned stimuli fail to awake it. Moreover, drugs such as caffeine (p. 916) which reduce internal inhibition, and those such as bromides which increase it, have corresponding effects upon the mechanism of sleep. As mentioned previously, positive conditioned reflexes after having been repeated over a long period ultimately undergo inhibition. At this stage in the investigations the experiment is frequently terminated by the animal falling asleep. Experiments involving the use of thermal and tactile stimuli are most frequently interrupted by the onset of sleep; auditory conditioned stimuli are the least likely to have this effect.

Protracted, mild stimulation of an extraneous nature has also been found to cause cortical inhibition and lead to sleep. It has been mentioned (p. 909) that an extraneous stimulus induces inhibition, through setting up an investigatory reflex; upon repetition, the inhibitory effect disappears, and the conditioned responses return. With further repetition, however, the extraneous stimulus again causes inhibition; this time, it exerts, of itself, a direct inhibitory effect upon the cortex.

Pavlov's theory has much to recommend it. The drowsiness which results from some oft-repeated form of monotonous stimulation, e.g., reading or being read to in a low even voice, a dull lecture, or boredom from whatever cause, is well known. Also, the preparations for sleep—the various agencies in a familiar environment—probably serve themselves as inhibitory conditioned stimuli. A dog, for example, which has fallen asleep during previous experiments may go to the same when merely brought into the room where the experiments had been performed or when preparations are being made to repeat them. The customary hour for retiring probably acts also as a time conditioned stimulus.

In some experiments described by Pavlov the inhibitory process involved the cortex but did not descend to subcortical levels governing equilibrium and the postural reactions of the skeletal muscles. The animal assumed a trance-like or cataleptic state in which muscular tone was retained, the general attitude being one of alertness. It stood with wide-open eyes but was quite unresponsive to all ordinary forms of stimulation. Pavlov looks upon this state as a transition stage between wakefulness and deep sleep, due to a less widespread diffusion of the inhibitory process, and similar in nature to hypnosis. It is suggested that during sleep, also, all cortical areas, analyzers as Pavlov terms them, are not necessarily under the inhibitory influence. The alertness of a mother, apparently in deep sleep, to the slightest noise made by her baby, is a case in point. In such an instance it is the auditory area or analyzer which has remained apparently outside the inhibitory influence.

These observations have undoubtedly some bearing upon the production of *dreams*. Dreams are evidently due to cortical activity since they involve memory and the ability to associate various sensory impressions. It is apparent, however, that it is the less critical areas of the cortex, i.e., those endowed with relatively crude analyzing and synthetic abilities, which are involved. The illogical, uncritical and often grotesquely absurd character of dreams is well known, yet the mental pictures are often drawn with great vividness, and a stimulus which in the waking state would leave little imprint upon consciousness is sometimes magnified enormously during sleep. As Descartes says, "A flea bit me and I dreamt of a sword cut!" Sensations arising in the viscera, such as those due to hunger, a distended stomach or bladder, thirst, etc., which during the day may cause no more than a passing thought may give rise to dreams filled with the most exciting events. It has been mentioned that dreams occur only during light sleep, that is, at a time when one would expect the internal inhibitory process to be restricted to the more highly specialized parts of the analyzers and before it has spread to involve the entire cortex. Dreaming may therefore be reasonably looked upon as being dependent upon a state of partial sleep—certain areas of the cortex being freed from the restraint which during the day is exercised by more critical regions.

(6) KLEITMAN'S THEORY. Kleitman has published a number of papers in the last few years on the subject of sleep. According to him, sleep is due to the inactivity of the cerebral cortex resulting from a reduction in the number of afferent impulses, especially from the muscles, reaching the sensorium. Fatigue of the neuromuscular mechanism mediating muscle tone, with consequent suppression of impulses from muscle proprioceptors, is considered to be the most important factor in the onset of sleep. According

to this author loss of muscle tone is an invariable prelude to sleep.

Kleitman claims to have demonstrated a diurnal variation in the speed, accuracy and steadiness with which certain muscular acts are performed. The efficiency of performance was maximal in the afternoon and minimal late at night and in the early morning. It is suggested that the variability is due to a corresponding rhythm in the tone of the skeletal musculature. But quite apart from these experiments, many observations give credence to the theory that cortical inactivity resulting from the blockage of afferent impulses is an important element in the onset of sleep. The exclusion of stimuli from visual, auditory and cutaneous receptors and the diminution of the flow of proprioceptor impulses as a result of muscular relaxation, are well-known means employed to induce sleep, whereas cortical activity, whether from psychic causes—*anxiety, worry, excitement, etc.*—or as a result of impulses set up in exteroceptors or muscle receptors, prevents sleep. In extreme fatigue when muscle tone is presumably at a minimum and the threshold of other afferent paths also probably raised as well, sleep comes on irresistibly. Kleitman and his associates found that after a prolonged period of wakefulness the only way in which they could keep from falling asleep was by moving about, or at least remaining in a standing or sitting position. Upon lying down and permitting their muscles to relax they were immediately overpowered by sleep.

An attempt has been made by Kleitman to reconcile the cortical theories of sleep with the undoubted fact that the hypothalamus is in some way concerned in the sleep process.

That sleep is not solely dependent upon the cortex is evident from the fact that decorticated dogs show periods of sleep alternating with intervals of wakefulness. The sleep rhythm in these animals is not, however, related in any way with night and day but consists of a number of shorter or longer periods throughout the twenty-four

hours. The sleep periods occur most constantly after feeding. During the waking periods the animals walk around almost incessantly. Lower orders in the animal scale in which the cortex is rudimentary and which, in consequence, are unable to develop a wide variety of conditioned responses show a similar sleep rhythm. This more primitive sleep mechanism is dependent conceivably upon a center located at a subcortical level, and most probably in the hypothalamus. We may regard it as presiding over vegetative functions and acting continuously to keep the animal asleep unless inhibited by impulses arising out of the more primitive processes and reactions, *e.g., hunger, thirst, cold or distension of the bladder or rectum.*

The diurnal sleep rhythm, that is, the ability to keep awake throughout the day, is dependent, on the other hand, upon the development of conditioned reflexes. So long as the cortex can bring its analyzing ability to bear upon the stream of impulses received from the different distance receptors, muscles, skin, etc., the functions of the primitive sleep center are held in abeyance. With the spread of internal inhibition over the cortex, or as a result of the elimination of stimuli from the periphery, the center asserts itself, and the subject is unable to remain awake. The diurnal sleep rhythm is therefore an acquired phenomenon—not inborn. Infants and very young animals do not show it but, like decorticated animals, have several sleeping periods throughout the day.

Those who believe that sleep results from the inhibition of a waking center in the hypothalamus take a somewhat different view. According to them sleep is a negative rather than a positive state, that is, it is due to the inactivity of the waking center. The activity of this center it is conceived is maintained by impulses received from the cortex. Cortical function is dependent in turn upon a flow of impulses along various afferent channels.

CHAPTER LXXI

THE CEREBELLUM

GENERAL STRUCTURE AND DIVISIONS

The cerebellum consists of a narrow central body, the *vermis* (or worm) and two lateral masses, the *right* and *left cerebellar hemispheres*. On its upper surface the demarcation between the vermis (*superior vermis*) and the hemispheres is slight. Upon the under surface the hemispheres are separated by a deep depression—the *Uccula*; the floor of the latter is formed by the inferior surface of the vermis. The inferior aspect of the vermis (*inferior vermis*) consists of four subdivisions, these are called in order from before backwards the *nodule*, *uvule*, *pyramid* and *tuber*. On either side and continuous with the nodule, is an elongated, somewhat lobulated structure called the *flocculus*. The cerebellar surface is not convoluted like the cerebral cortex but is divided by parallel and curved furrows into numerous *pinnae* or *folia*. The total cortical area of the human cerebellum is about 100,000 sq. mm., or less than half that of the cerebral cortex.

Though the division of the cerebellum into the vermis and two hemispheres possesses considerable descriptive value, comparative neurologists (chiefly Bolk, Ingvar, Elliott Smith and Larsall), have suggested other divisions which possess greater significance from a phylogenetic and functional point of view. In Larsell's description (see fig. 382) the cerebellum is divided into two fundamental or primary parts, (a) the *flocculonodular lobe* or *vestibulo-auricular part*, and (b) the *corpus cerebelli* which is predominantly concerned with the integration of proprioceptive impulses (from the muscles). These two parts are separated by a deep fissure—the *posterolateral fissure*—which is present in all vertebrate brains.

The *flocculonodular lobe* which comprises the *flocculus* and the *nodule* is developed from the structures in the region of the vestibular nuclei. The *corpus cerebelli* includes all the rest of the cerebellum, i.e., the portion lying above and in front of the posterolateral fissure. It is subdivided by a well-marked fissure—the *fissura prima* (of Elliott Smith)—into an anterior and a posterior lobe. The *anterior lobe* consists of three subdivisions; the *lingula*, *lobulus centralis* and *culmen*. The *posterior lobe* includes the *lobulus simplex*, *declive*, *pyramid* and *uvule*, together with the associated parts of the hemispheres (*lobulus ansiformis* and *lobulus paramedianus*, see below) and the *parafocculus* (fig. 382). The *flocculonodular lobe* (vestibular function), the *anterior lobe* of the *corpus cerebelli*, and the *nodule*, *pyramid* and *parafocculus* of its posterior lobe are physiologically old (*paleocerebellum*). The remainder of the cerebellum, namely, the greater part of the hemispheres, and the *superior vermis* are later

acquisitions (*neocerebellum*), appearing coincidentally with the development of the pyramidal tracts. The *neocerebellum* is absent or rudimentary in submammalian forms.

The small compact mass situated on either side of the inferior vermis is known as the *tonsil* or *paramedian lobule*, and that lying immediately behind the *fissura prima*, as the *lobulus simplex*. The remainder of the hemisphere belonging to the posterior lobe of the *corpus cerebelli* is known as the *ansiform lobule*. The latter shows its greatest development in the human brain, its function apparently being concerned with the tonus adjustments required in the performance of skilled muscular movements.

INTERNAL STRUCTURE

When sectioned in the sagittal plane each hemisphere of the cerebellum presents a branching core of white matter which from its foliage-like appearance, has been named the *arbor vitae*. The terminal branches of the white matter are covered with a coating of gray substance which constitutes the cerebellar cortex. The leaf-like structures so formed are spoken of as *folia*, and are responsible for the laminated appearance of the cerebellar surface (fig. 383). Unlike the cortex of the cerebrum the cerebellar cortex shows a uniform histological structure throughout its extent.

The gray matter

THE CORTEX. Three cell layers are distinguished.

(1) *The molecular (or plexiform) layer* is outermost and consists largely of unmyelinated nerve fibers derived from (a) the white substance, (b) the cells of the two underlying layers, and (c) the cells within this layer itself. The cells of the molecular layer are arranged in a deep and a superficial stratum, their axons synapse with the Purkinje cells, whose dendrites arborize throughout this layer. The cells of the superficial stratum are small, star-shaped and few in number. The deep stratum is composed of larger stellate cells whose axons run transversely in relation to the long axis of the folium and arborize by means of collaterals around the bodies of several Purkinje cells. They are referred to as "basket" cells (see fig. 384).

(2) *The intermediate layer of Purkinje cells.*

FIG. 382. Diagram of the cerebellum showing its division into a flocculonodular lobe (stippled area) and a corpus cerebelli (blank area) consisting of an anterior and a posterior lobe. (After Larsall.)

The large flask-shaped bodies of these cells, which are peculiar to the cerebellum, form a layer between the molecular and the granular layers. Their dendrites pass outwards into the molecular layer where they arborize luxuriantly; as just mentioned, collaterals of axons of the basket cells arborize around their bodies. The axons of the Purkinje cells enter the white substance, and end by synapsing with cells in the cerebellar nuclei. The Purkinje arborizations extend outwards through the entire thickness of the molecular layer. They are spread out or flattened in the transverse plane of the folium, thus resembling a vine trained

FIG. 383. Diagram of the cerebellar peduncles (redrawn from Villiger).

FIG. 384. Diagram to show structure of cerebellar cortex. G, granule cell; B, "basket" cell.

against a wall rather than a bush. The body of the cell is flattened in a similar manner.

(3) *The granular layer*, which rests upon the white matter, is composed of small, round, closely packed cells, and numerous nerve fibers. The cells possess four or five dendrites which end in a network of branches close to the cell body and connect with those of neighboring cells. One long process (axon) of each extends into the molecular layer where it connects with the dendrites of a large number of Purkinje cells. Afferent fibers ("moss fibers," p. 924) arriving via the inferior cerebellar peduncles make connections with the granule cells.

The cerebellar nuclei

The cerebellum contains on either side four separate gray masses. These are: (a) the *nucleus dentatus*, (b) the *nucleus emboliformis*, (c) the *nucleus globosus*, and (d) the *nucleus fastigii* (or *nucleus*) (fig. 385). The first three of these nuclei lie embedded in the white matter of the hemisphere. They receive the axons of Purkinje cells; their constituent cells give rise to fibers which leave the cerebellum via the superior cerebellar peduncles. The dentate nucleus is the most recently acquired of the cerebellar nuclei. Afferent fibers are derived mainly from the cortex of the hemispheres (lobus ansiformis). The roof nuclei are phylogenetically older than those of the other nuclei; they are situated in the white substance of the anterior part of the superior hemisphere, one on either side of the mid-line. They give off fibers from the cortex of the vermis (pyramis, uvula and nodule) and are closely associated with the vestibular nuclei to which they send, and from which they receive fibers, via the inferior cerebellar peduncles. The fastigial nuclei are regarded as centers for the integration of vestibular and spinocerebellar impulses. Fibers from the vestibular nuclei also pass to the nucleus emboliformis and nucleus globosus.

The white matter

The white matter of the hemispheres is composed of: (a) *projection fibers*, i.e., fibers which leave the cerebellum via the peduncles, (b) *association fibers*, which connect different regions of the same hemisphere, and (c) *commissural fibers* connecting cortical areas of the two hemispheres. The projection fibers—both afferent (to the cerebellum) and efferent (away from the cerebellum)—are in three bundles on each side which connect the cerebellum with the rest of the central nervous

system. These bundles are known respectively as the *superior*, *middle* and *inferior cerebellar peduncles*.

THE CEREBELLAR PEDUNCLES (SEE FIGS. 383 AND 386)

THE INFERIOR PEDUNCLES (RESTIFORM BODIES). Its fibers are predominantly afferent and convey non-sensory impulses from the labyrinth, joints and voluntary muscles. Its constituent fiber tracts are:

A. Afferent (entering) fibers

(1) *Dorsal spinocerebellar (direct cerebellar) tract*. The fibers of this tract end in the cortex of the anterior and posterior lobes of both sides but mainly of the same side. Some fibers also end in the nodule.

(2) *Dorsal external arcuate fibers* (p. 851) from the nuclei gracilis and cuneatus of the same side, and the *ventral external arcuate fibers* from the corresponding nuclei of the opposite side. These fibers end in the cerebellar cortex but their precise distribution is unknown.

(3) Fibers from the sensory nuclei of the *trigeminal*, *facial*, *vagus* and *glossopharyngeal nerves*.

(4) *Vestibulocerebellar tract* from the vestibular nuclei of the same side, and also directly from the vestibular nerve. They pass to the three cerebellar nuclei (nucleus globosus, nucleus emboliformis and nucleus fastigii) and are relayed to the cortex of the flocculonodular lobe and of the uvula.

(5) *Olivocerebellar tract* arising in the inferior olive of the opposite side and to some extent in the nucleus of the same side; the fibers of this tract end in the cortex of those portions of the vermis and hemispheres constituting the posterior lobe.

B. Efferent (leaving) fibers

(1) *Cerebellovestibular tract*. This is constituted of efferent fibers which arise from the nucleus fastigii, and end in the vestibular nuclei of the same side. Thence impulses may pass via (i) the vestibulospinal tract to the spinal centers and (ii) the medial longitudinal fasciculus to the nuclei of the ocular nerves and into the anterior ground bundle of the cord.

(2) *Cerebello-olivary tract* to the inferior olives of both sides. The latter are connected with the spinal centers through the olivospinal tracts (p. 856).

(3) Fibers to the reticular formation of the medulla from which impulses are relayed to (i) the motor nuclei of the cranial nerves, and (ii) spinal centers (via the reticulospinal tract).

THE MIDDLE PEDUNCLES (BRACHIA PONTIS) are also mainly afferent. Each contains:

(a) fibers which arise from cells of the pontine nuclei and end in the cortex of the posterior cerebellar lobe

(hemisphere) of the opposite side. These fibers constitute the secondary neurons of the *temporopontine-cerebellar* and the *frontopontine-cerebellar* tracts; (b) fibers which pass from the cerebellar nuclei to the hemisphere of the opposite side (see fig. 386).

THE SUPERIOR PEDUNCLES (BRACHIA CONJUNCTIVAE) enter into the formation of the upper part of the roof of the 4th ventricle and plunge into the mid-brain just beneath the inferior colliculi. The superior cerebellar peduncle contains both efferent and afferent fibers but is composed predominantly of the former. It is through the superior peduncle that the cerebellum exerts its main influence upon the skeletal musculature.

FIG. 385. Diagram of a horizontal section through the cerebellum to show the cerebellar nuclei (viewed from in front).

A. *The efferent fibers* arise from all the cerebellar nuclei with the exception of the nucleus fastigii. The Purkinje cells constitute the primary neurons of these paths. The fibers decussate in the mid-brain with those of the opposite side and then divide into an ascending and a descending group.

(1) *The ascending fibers:* (a) terminate in the nucleus parvocellularis and nucleus magnocellularis of the red nucleus; impulses from the large-celled nucleus are relayed via the rubrospinal and the rubrobulbar tracts to the cranial nuclei and the spinal centers of the opposite side; (b) pass to the lateral part of the lateral nucleus of the thalamus and are relayed to the cerebral cortex.

It will be noted that the ascending fibers connect one cerebellar hemisphere with the red nucleus, thala-

mus and cerebral cortex of the opposite side, but, as a result of the crossing of the rubrospinal and pyramidal (corticospinal and corticobulbar) tracts, each cerebellar hemisphere is ultimately connected with the same side of the brain stem and spinal cord.

(2) *The descending fibers* terminate around cells of the reticular formation of the pons, medulla and cervical cord.

B. *The afferent fibers* of the superior cerebellar peduncle are:

(1) The ventral (indirect) spinocerebellar tract. This ascends through the medulla and pons and reaching the upper level of the latter turns backwards, arches over the peduncle, enters the anterior medullary velum, and passes within this to the cerebellum.

The fibers end in the cortex of the anterior lobe mainly of the same side.

(2) *The tectocerebellar tract*, composed of fibers which originate in the superior colliculus. It probably conveys retinal impulses and so constitutes a pathway for visuocerebellar reflexes. This tract has not been demonstrated in man.

The fibers reaching the cerebellar cortex via the peduncles are of two main types: (a) "*moss fibers*," which end in moss-like appendages around the cells of the granular layer (fig. 384) and (b) *climbing fibers*, which pass outward to the molecular layer; here they give off collaterals resembling the tendrils of a vine which appear to cling to the arborizations of the Purkinje cells. According to Caja the

climbing fibers are derived from the vestibular and pontine nuclei; while the direct spinocerebellar and olivocerebellar tracts are constituted of moss fibers. Through their connections with the cells of the granular layer each moss fiber is connected indirectly with a large number of Purkinje cells, whereas a climbing fiber is in communication with only one or two Purkinje cells.

THE EXPERIMENTAL STUDY OF THE CEREBELLUM EFFECTS OF EXCISION OF THE CEREBELLUM AND OF SECTION OF THE PEDUNCLES

Luciani's extirpation experiments are classical. This observer has described the results of his operations upon dogs and monkeys as occurring in three stages.

In the *first stage* or "*dynamic phase*" which lasts for from 6 to 10 days the animal showed restlessness and agitation and, when the cerebellar removal was complete, increased tone of the muscles on both sides of the body. There were also observed *extension and abduction* of the forelimbs, *clonic movements* of the hind limbs, *retraction of the head with hyperextension of the back* (opisthotonos) and *convergence of the eyes*. *Horizontal nystagmus* also occurred in some cases. In the monkey the effects upon the neck and back muscles caused the animal to *fall backwards* when it attempted to assume an erect position. Unilateral ablation was followed by tonic spasm of the muscles on the operated side with consequent curvature of the body with its concavity towards that side (pleurothotonos), rotation of the head and neck and of the body around its long axis towards the healthy side, and tonic extension of the ipsilateral forelimb with clonic movements of the other three limbs. After unilateral ablation there may also be slight nystagmus and a squint with downward and inward deviation of the eye on the operated side, and outward and upward deviation on the healthy side (*skew deviation*). These effects of the dynamic phase are probably release phenomena, i.e., the result of the sudden removal of cerebellar inhibitory influences upon other mechanisms (e.g., labyrinthine) governing muscle tone and not, as might be thought, the result of the irritation of divided nerve tracts.

The *second stage* is marked by "deficiency" phenomena; that is to say, the overactivity of other parts of the nervous system, as a result of their release from cerebellar influence, has largely disappeared and symptoms, which depend more directly upon the loss of cerebellar function (p. 928), become more prominent. This stage has been analyzed by Luciani into three components to which he has given the names (a) *asthenia*, (b) *atonia* and (c) *astasia*.

By *asthenia* is meant the muscular weakness which in the earlier part of the second stage renders the animal unable to stand. There is no actual paralysis, however, for the animal is able to swim well and with perfect coördination, since the weight of the body is then supported by the surrounding water.

Under the term *astasia* is included the unsteadiness of the muscles, which gives rise to coarse involuntary effort, they are therefore referred to as *intention tremors*. Other manifestations of cerebellar deficiency are jerkiness and incoördinate action of the muscles (*asynergia*, p. 929). The gait when the animal first recovers its ability to walk is reeling or staggering in character; the head pendulates or oscillates from side to side. When the ablation is unilateral the muscular defects on the operated side cause the animal to fall to that side. As a result of the lowered muscular tone on

the operated side the body is curved towards the healthy side. The animal in consequence while swimming or walking tends to circle towards this side.

The defects in voluntary muscular control, namely, the tremor, the asynergic action of the muscles and the abnormalities of gait are referred to collectively as *cerebellar ataxia*.

In the *third stage* compensation develops. There is a gradual diminution of the deficiency phenomena (organic compensation) together with abnormal movements directed towards counteracting or neutralizing the effects of the cerebellar deficiency (functional compensation).

Cerebellar removal causes no effect upon consciousness or upon any form of sensation.

EFFECTS OF SECTIONING THE PEDUNCLES. Division of all three peduncles of one side causes defects identical with those following unilateral cerebellar ablation. *Asynergia*, *fatiguability* and *hypotonia* of the muscles, together with a coarse *tremor*, appear on the same side as the lesions. Somewhat similar though less severe effects follow the severance of one superior cerebellar peduncle. Compensation occurs through the remaining cerebellar connections (Walker and Botterell), especially through the corresponding peduncle of the opposite side. Even after unilateral section of the three peduncles, compensation is brought about after a time through the remaining half of the cerebellum and through the frontal lobes (Botterell and Fulton).

The experiments of Aring and Fulton indicate that the nervous mechanism involved in the production of the tremor lies in the excitable part of the cerebral cortex (area 4 and the upper part of area 6a); removal of these areas after contralateral section of the cerebellar peduncles abolished the tremor. The ability to compensate for cerebellar defects depends, apparently, upon the premotor area (area 6a, upper part). Removal of this area was followed by marked accentuation of the cerebellar signs and permanent impairment of the animal's ability to compensate for the cerebellar defect. These findings suggest that the "cerebellar" signs which are sometimes seen clinically in lesions of the frontal lobe are probably due to involvement of the premotor cerebellar connections (frontopontine-cerebellar tract). On the other hand, removal of the motor area (area 4) alone, temporarily abolished and permanently depressed the manifestations of cerebellar deficiency.

CEREBELLAR LOCALIZATION AS DETERMINED BY REGIONAL STIMULATIONS AND ABLATIONS. Localization in the cerebellum appears to be on a purely functional basis. That is to say, the cerebellum, unlike the motor area of the cerebral cortex, cannot be mapped out into circumscribed regions, each correlated with the movements of a discrete group of muscles in some one or other part of the body. The most that can be said for an anatomical or spatial relationship between the cerebellum and the peripheral parts of the body is that it exerts its influence mainly ipsilaterally, i.e., a given half of the cerebellum acts predominantly upon the muscles of the same side of the body, that the anterior lobe exerts an influence upon the postural musculature of the head and neck, the ansiform lobe affects the muscles of the upper limb and the uvule and pyramid the muscles of the trunk. The hemispheres are concerned mainly with the integration of voluntary movements.

In the decerebrate animal a weak faradic current applied to the cortex of the *anterior lobe* of the corpus cerebelli causes a reduction in extensor rigidity on the same side. The effect is most pronounced in birds. It is quite evidently due to stimulation of the cortex itself and not to the spread of the current to deeper structures (e.g., nuclei) since the response is annulled by cortical anemia or by the application of cocaine. Miller and Banting observed, occasionally, walking movements upon weak stimulation of the superior surface of the vermis (anterior lobe) which suggests that this part of the cerebellum exerts an excitatory as well as an inhibitory influence.

Excision of the cortex of the *anterior lobe* enhances postural mechanisms, increasing the stretch reflexes (p. 822) and the positive supporting reactions. The responses of the antigravity muscles are exaggerated. Hyperactivity of the extensors of the back causes extreme opisthotonus. Excision of any part of the anterior lobe (with the exception of the lingula) does not cause any noteworthy disturbance of gait or balance.

Electrical stimulation of the cortex of the hemispheres causes no obvious excitatory or inhibitory effect, though a rise in excitability of the motor area of the cerebral cortex can be induced by this means, and Miller found that the application of a 1 per cent solution of strychnine to the surface of the cerebellar hemisphere caused increased extensor tone and clonic movements of the limbs, chiefly of the same side. The effects following unilateral excision of one hemisphere (monkey) or its decortication are surprisingly slight, consisting of

hypotonia, some difficulty in the execution of skilled muscular acts and disturbances of gait (Botterell and Fulton). These defects involve both limbs on the same side as the lesion and are transient, persisting for only a few days (1 to 2 weeks). Similar effects, but more pronounced, followed bilateral excision of the hemispheres and in addition a slight tremor which lasts for a day or two. Botterell and Fulton conclude that the restoration of function is due to compensation through other parts of the cerebellum. Keller and his colleagues, on the contrary, found that complete bilateral removal of the cortex of the neocerebellum (p. 921) in dogs and monkeys caused no functional disturbance, even of a transitory nature, and concluded that when such effects do appear they are due to coincident injury of other cerebellar parts and that the "*neocerebellum is not essential for any of the functions that have been attributed to the cerebellum.*"

Ablation of the *nodule* and *flocculus* (flocculonodular lobe, p. 921) in monkeys or of the nodule and part of the uvule (Dow) which causes injury to vestibular paths, is followed by pronounced disturbances of balance. In man a lesion of this part of the vermis is also associated with disturbances of equilibrium. e.g., "forced" falling. Removal of the *nodule* alone in monkeys is followed by oscillation of the head and neck (and, in some instances of the whole trunk) forced falling backwards and an abducted gait. Ablation of the *uvule* alone is followed by some transient disturbance of equilibrium but destruction of the *pyramid* causes no defect of balance. But this part of the cerebellum is concerned in some way with vision. Its loss in the monkey results in an inability to halt its forward progression in time to prevent it from crashing into some obstacle. Faradic stimulation of the pyramid elicits an upward movement of the eyes, and Fulton suggests from this fact and the preceding observation the possibility of the pyramid being concerned in some way with the integration of proprioceptive impulses essential in judging distance.

STIMULATION OF THE CEREBELLAR NUCLEI

The following is a summary of the results obtained by Miller and Laughon.

(a) Faradic stimulation of the *nucleus dentatus* causes increased tone of the flexor muscles of the ipsilateral limbs (biceps brachii and tibialis anticus) together with inhibition of the tone of the extensor muscles (lateral head of the triceps, gastrocnemius and soleus). There is increased tone of the trunk muscles

of the stimulated side with consequent curvature of the body. There is no after discharge in the case of the limb flexors; "rebound" occurs in the extensors after cessation of the stimulation.

(b) Stimulation of the nucleus emboliformis, globosus or fastigii causes similar but more intense responses. Ocular movements may occur. In the case of the nucleus fastigii strong flexion of both forelimbs may result.

The efferent pathways for these reactions are via the superior peduncle, red nucleus and rubrospinal tracts in the case of the nuclei dentatus, emboliformis and globosus, and through the inferior peduncle, vestibular (Deiter's) nucleus and vestibulospinal tract in the case of the nucleus fastigii.

THE FUNCTIONS OF THE CEREBELLUM

The similarity between the effects of labyrinthectomy and cerebellar lesions, taken together with the intimate anatomical connections between the cerebellum and the vestibular nuclei, would naturally lead one to suppose that the primary function of the cerebellum is the maintenance of equilibrium. It seems clear, however, that the cerebellum is not concerned specifically with this function. Magnus and his associates have shown that all the labyrinthine and other righting reflexes can be carried out unaltered after complete removal of the cerebellum. It appears indeed that the cerebellum actually exerts an inhibitory influence upon the labyrinthine reflexes since Pollock and Davis found them to be more active after decerebellation. Luciani, who denied that the function of the cerebellum was one concerned primarily with the maintenance of equilibrium of the body and its orientation in space, attributed the disturbances of posture simply to weakness, hypotonia and incoördination of the muscles (p. 926). He pointed out that the blindfold decerebellate dog swims with good orientation, when thrown into water. The blindfold labyrinthectomized animal (cerebellum intact), when treated similarly, drowns (p. 831). It is not now believed that the cerebellum exerts any specific or direct effect in coördinating the actions of the different muscles engaged in a voluntary movement, i.e., of timing their contractions. The jerkiness and irregularity of muscular action seen in cerebellar disease and which is referred to as ataxia, is thought to be largely due to the weak and hypotonic state of the muscles rather than to a failure of coördination. "It will not suffice to speak of coördination as a separate faculty, coördination is the function of the whole and every part of the nervous system" (Hughlings Jackson).

What then are the functions of the cerebellum?

We have seen that it receives non-sensory impulses from the muscles of the limbs, trunk, face, etc., and from the labyrinth, and that it is connected in turn with the muscles by efferent tracts. The cerebellum has been described as "the head ganglion of the proprioceptive system" (Sherrington). This does not mean, however, that it is a center through which the various postural reflexes are actually carried out. The augmentation of the labyrinthine reflexes after cerebellar removal, and the fact that decerebrate rigidity is not abolished after decerebellation but is inhibited by stimulation of the cerebellar cortex, provide evidence to the contrary. Moreover, tonic and phasic reflexes and regular rhythmic reflexes are carried out in the decerebrate animal after cerebellar removal.

The cerebellum exerts, rather, a modifying or regulating influence upon muscular activity whose primary centers are situated in other parts of the brain or in the spinal cord. Through its connections with the motor neurons of the brain and cord the muscles receive impulses of either an inhibitory or an augmentor nature, depending upon the conditions at the moment. Through these connections those finer adjustments of tone and the appropriate distribution of tone between groups of muscles which are essential for the maintenance of posture and for the accomplishment of complicated and precise voluntary movements are brought about. In other words, upon the general background of tonus established through centers in the cord or brain the cerebellum makes the final delicate adjustments which enable the various muscle groups to act smoothly and harmoniously, i.e., as a coöperative whole, in a given movement.

Following Beevor, the muscles concerned in a voluntary muscular act may be classed in three groups:

(a) PRIME MOVERS OR AGONISTS, those whose contraction is essentially responsible for the movement of the part.

(b) ANTAGONISTS, those which oppose the prime movers.

(c) SYNERGISTS, those which assist the prime mover and reduce unnecessary movements to a minimum.

(d) FIXATION MUSCLES, those whose contraction causes the fixation of the neighboring joints and maintains the limb or body in a position appropriate for carrying out the particular movement.

Normally these muscle groups act as a unit. The contraction of the prime mover, e.g., the biceps, is accompanied by inhibition of the contraction of its antagonist, i.e., the triceps. The re-

al inhibition, however, is not absolute; the antagonistic muscle as shown by Tilney and Pike, gives a coincident but weaker contraction, and thus serves the function of a "brake" or "snubber" to check the action of the agonist. At the same time the fixation muscles of the neighboring joint contract, thus enabling the agonist to exert its force with a minimum of waste effort. Any increase in the force of contraction of the agonist is accompanied by a corresponding rise in tone of its opponent (antagonist). Also, the muscles of fixation and the synergists contract more powerfully as the contraction of the prime movers increases, while groups of fixation muscles and synergists, which in weaker movement remain quiescent, may be called into play. To give an example, when the fingers are closed with moderate force the only fixation muscles which show activity are the extensors of the wrist. When, however, the fist is clenched forcibly, muscles of the elbow and even those of the shoulder contract to fix these joints. Through such action between the various muscles taking part in a given act, smoothness and steadiness of movement are ensured and muscular force thereby economized. After destruction of the cerebellum these nice coöperative actions are lost. The asynergia results in jerkiness, overaction and imperfect muscular control (ataxia).¹

Since it is in the conscious and not in the decerebrate animal that cerebellar removal shows its outstanding effects, it seems clear that the cerebellum is concerned mainly with voluntary movements, and with those semi-voluntary or automatic movements which are the basis of postural adjustments. It is the chief assistant of the higher motor centers. In order to be of full assistance it must, on the one hand, be in communication with labyrinthine and muscle proprioceptors (vestibulocerebellar and nococerebellar tracts) and, on the other, be informed of the "intentions" of the cerebral cortex. The cerebropontine-cerebellar tracts provide the probable paths along which intelligence of the projected plan of the cortex in any voluntary movement is transmitted to the cerebellum. The cerebellum sends messages in turn through its superior olivuncles to the cerebral cortex (via the thalamus) which may reinforce or strengthen, and perhaps modify in other ways, the discharge from the motor

Holmes denies that the cerebellum exerts any specific function in respect to the distribution of tone among various muscles acting synergically. The steady action which tonic muscles normally exert on their antagonists is absent in cerebellar disease but Holmes maintains that this is due merely to the general atonicity.

area itself. It is probably through the cerebello-rubro-spinal pathway that the cerebellum exerts its chief synergizing action upon the muscles, adjusting their tone, appropriately as to time, strength and distribution, to the voluntary discharge.

THE MANIFESTATIONS OF CEREBELLAR DISEASE

The signs of cerebellar disease are much more pronounced in acute lesions, e.g., abscess, hemorrhage or trauma, than in those, e.g., tumor, which develop more gradually. In slowly developing lesions or after the subsidence of acute cerebellar disease a certain degree of compensation for the cerebellar defect always occurs. The majority of the signs of cerebellar disease are the result fundamentally of asynergia of the voluntary muscles.

Following Holmes, the chief features of cerebellar lesions will be considered under the following headings: (1) *hypotonia*, (2) *asthenia, fatigability and slowness of movement*, (3) *tremor*, (4) *asynergia*, (5) *decomposition of movement*, (6) *dysmetria*, (7) *rebound phenomenon*, (8) *adiadochokinesis*, (9) *vertigo and past-pointing*, (10) *deviation of the eyes and nystagmus*, (11) *attitude and gait*, (12) *disturbances of speech*, (13) *reflexes*.

HYPOTONIA. This is usually a prominent feature in acute cerebellar lesions. The muscles are flabby. The limbs for this reason assume unnatural attitudes and can be moved passively into positions of extreme flexion or extension. The extremities flop about when shaken vigorously and, if the patient is suddenly rotated when standing, the arms swing loosely from the shoulders.

ASTHENIA, FATIGABILITY AND SLOWNESS OF MOVEMENT. The muscles on the affected side are definitely weakened and tire easily. The commencement of any voluntary movement is delayed, and both contraction and relaxation phases are abnormally slow. Neither hypotonia nor asthenia are notable features in chronic lesions and it is probable that in acute lesions hypotonia is not a result of the cerebellar defect itself but of the involvement of neighboring structures. It will be recalled that hypotonia was not observed by Magnus nor by Aring and Fulton after decerebellation. Some also question whether asthenia is a manifestation of cerebellar deficit, but Holmes considers it to be due to involvement of the cerebellar nuclei.

TREMOR. This is a coarse involuntary jerking which is increased by voluntary effort. It is due evidently to the loss of the steadying effect which

increased tonus of the antagonistic muscles normally affords to voluntary movements.

ASYNERGIA. It should be pointed out that this term as used by Holmes has a much more restricted meaning than that which is usually given to it. This observer applied the term especially to the asynchronism observed between the actions of the fixation muscles and the prime movers, as well as to the lack of coöperation which normally exists between the muscles of the limbs, trunk and neck during walking and standing, and other acts necessitating postural adjustments of the various members of the body against gravity. For example, when the patient is asked to clench his fist, the extensors which normally fix the wrist as the fingers are flexed, either contract too early, and so over-extend the joint, or too late. In the latter event the wrist is flexed as the fist closes. Also, the patient may fall when he throws his head back owing to his failure to flex his knees, and so maintain his center of gravity over his base. Similarly when he attempts to sit upon a low stool he may fall backwards because he cannot at the same time flex his trunk at the hips.

DECOMPOSITION OF MOVEMENT. The patient performs acts "by numbers," to use a military expression. When, for example, he is asked, as he lies in bed, to extend his arm vertically, and then to touch his nose with his forefinger, the latter movement is not performed naturally by simultaneously lowering the arm and bending the elbow. The extended arm is first lowered to the side; not until this position is reached is the elbow flexed and the finger brought to the nose.

DYSMETRIA is the lack of ability to adjust the force of the contraction necessary for the accomplishment of a given act. For example, when asked to touch a point with his finger the patient overshoots the mark or, less commonly, fails to reach it. Dysmetria in a lower limb may be demonstrated by the heel to knee test; when the patient, while recumbent, is directed to rest the heel of the affected side upon the opposite knee, he brings it in contact with the thigh or with the leg below the knee. Dysmetria is another manifestation of the general lack of synergic muscular control.

REBOUND PHENOMENON. If the patient is asked to attempt a movement against a resistance which is then suddenly removed, the limb moves forcibly in the direction towards which the effort was made. For example, if the observer holds the wrist of the patient, then asks him to bend the elbow, and, while he is making the effort, the forearm is sud-

denly released, flexion of the arm occurs with an unusual degree of force. This rebound phenomenon can be attributed to the absence of the "braking" action (p. 929) of the antagonistic muscles.

ADIADOCHOKINESIS (a = primitive; diadocho = succession, kinesis = movement) is the name given by Babinski to the inability to execute alternating movements rapidly, e.g., pronation and supination of the forearm, or flexion and extension of the fingers.

VERTIGO AND PAST-POINTING (pp. 841, 843). When the patient with his eyes closed is asked to raise the arm of the affected side and touch a prescribed mark the arm deviates outwards, rarely inwards. When directed to move the finger in the horizontal plane and touch the mark the arm in some cases, deviates upwards, in others downwards.

DEVIATION OF THE EYES AND NYSTAGMUS. In an acute unilateral lesion there may be conjugate deviation of the eyes to the uninjured side. When the patient is asked to look at an object in front of him the eyes move into position but then slowly deviate again to the uninjured side; after full deviation the eyes may return again to the central position with a sharp jerk. These alternate horizontal movements occur repeatedly and are known as nystagmus (p. 838). Though no deviation of the eyes is evident, nystagmus can sometimes be demonstrated in the subject of a cerebellar lesion when he is asked to turn his eyes towards either the injured or the uninjured side; the eyes are moved in the direction indicated and then deviate slowly towards the mid-line, only to be returned in a series of jerks toward the point in which he is attempting to look. The nystagmus is due to injury of vestibulo-cerebellar paths. (See also p. 845.)

Skew deviation of the eyes (p. 926) is sometimes observed in acute cerebellar disease.

ATTITUDE AND GAIT. Cerebellar disease sometimes results in abnormal attitudes. The trunk may be concave towards the affected side and sometimes rotated with the affected shoulder advanced. Rotation of the head with the chin towards the sound side, and flexed towards the shoulder of the affected side is not uncommonly seen in unilateral cerebellar disease. (This attitude is probably due to an associated lesion of the vestibular paths in the brain stem.) In standing the body is inclined towards the side of the lesion and tends to fall on that side. Falling backwards or forwards may occur (especially in lesions of the vermis). The abnormal attitudes of the limbs resulting from muscular hypotonicity when this is present, have been mentioned.

The gait is often staggering, reeling or lurching in character. The patient's line of travel is not straight but tends to be curved; the deviation is towards the affected side. When he is able to see his way he attempts to correct his tendency to deviate to one side by bringing himself back from time to time to his intended line of travel. Thus he follows a zig-zag course to his objective. The movements of the lower limbs are ataxic; they are often thrown about in an awkward, uncontrolled manner; the feet are raised unnecessarily high and brought down again clumsily, often in a clapping fashion.

Weisenburg has studied the gait of subjects of cerebellar disease by means of slow moving pictures. The gait was found to vary according to the muscle groups involved. When the muscles of the entire trunk are affected, the patient frequently is unable to stand or walk, and, when walking is attempted, the limbs are thrown out in almost any direction. If the muscles of the pelvic girdle alone are involved, the trunk is held rigidly erect and the lower limbs are thrown forward from the pelvis, the upper part of the body appearing to be led by the legs. When the shoulder girdle alone is involved there is less difficulty in standing or walking. The subject holds his legs wide apart and when walking, lurches in one or other direction, the upper part of the body leading and appearing to draw the legs after it.

DISTURBANCES OF SPEECH are due to asynergia of the muscles of phonation and articulation. It is seen most frequently in lesions of the vermis. The speech abnormality may be drawling, scanning, sing-song or explosive in type.

THE REFLEXES. The cutaneous reflexes are normal and the deep reflexes, with the exception of the knee jerk, show as a rule no marked departure from the normal. The knee jerk is not uncommonly pendular in character. That is to say, when the leg is hanging free a tap on the patellar tendon causes a slower, less brisk response than normal, but one of greater amplitude. Also, unlike the response of the sound side, the return excursion of the leg is not arrested when, as a result of the influence of gravity, it reaches the resting position, but swings beyond. Several to and fro movements follow before the limb finally comes to rest. This behavior is evidently due to the hypotonicity of the flexor and extensor muscles and thus to a lack of the restraining effect which they normally exert upon one another to prevent exaggerated excursions of the limb in either direction.

Muscle sense and other forms of sensation are unaffected in cerebellar disease. The following are the principal types of cerebellar lesion: (1) *Tumor*, (2) *abscess*, (3) *injury*, e.g., gunshot wounds, (4) *degenerations* of (a) the cerebellar cortex, (b) the middle and inferior peduncles, (c) more rarely, of the cerebellar nuclei and superior peduncles, (d) of the spinocerebellar tracts, e.g., Friedreich's ataxia, a hereditary condition.

A lesion involving the neocerebellum (superior vermis and hemispheres) is associated with hypotonia; dysmetria; weakness, slowness and irregularity of voluntary movement; tremor and nystagmus. In disease of the flocculonodular lobe, there are marked disturbances of balance with a swaying, staggering gait and a tendency to fall backwards.

CHAPTER LXXII

THE CEREBROSPINAL FLUID (C.S.P.)

The discovery of the cerebrospinal fluid is generally ascribed to Cotugno (*Liquor Cotunnii*) but the first clear description was provided some fifty years after Cotugno's report by Magendie (1825).

Anatomical considerations

The dural and the arachnoid membranes form the meningeal covering of the sac which contains the cerebrospinal fluid. The fluid circulates in the subarachnoid space which is for the most part narrow but is widened into spaces (*cisterna*) at several points. The principal dilatations are the *cisterna magna* below the cerebellum and above the medulla, the *cisterna pontis* on the ventral aspect of the pons and the *cisterna basalis*, which contains the circle of Willis. The subarachnoid space is lined with flattened epithelial cells and, at intervals, particularly in association with arachnoid villi, clumps of phagocytic cells called *meningocytes* which stain like the cells of the reticulo-endothelial system are found.

Site of formation

In 1853 Faivre reported the results of a histological study of the villous projections of the chorioid plexuses into the ventricles of the brain. He found evidence of secretory activity in the cells covering these vascular structures. While this observation served to turn the attention of physiologists from the concept of Haller and Magendie, who believed that the fluid was formed by the leptomeninges, the evidence that the chorioid plexuses are the principal structures concerned was not obtained until quite recently. While further histological and pharmacological studies gave additional support for this view, physiological experiments and observations on human cases have provided more conclusive results. Some of the more significant results will be cited: (1) When the aqueduct of Sylvius is occluded an internal hydrocephalus is produced (Dandy and Blackfan; Frazier and Peet); (2) during an operation on a human case a clear fluid was observed exuding from a choroid plexus (Cushing); (3) a sustained outflow of fluid, similar in volume to that obtained from the subarachnoid space was secured from a catheter inserted into the

aqueduct of Sylvius (Weed); (4) a unilateral internal hydrocephalus can be produced by obstructing one foramen of Monro (Dandy) but there is no excess accumulation of fluid when the chorioid plexus is removed from the lateral ventricle before the obstruction is produced. These points leave no doubt of the importance of the plexuses in the elaboration of the fluid but there is suggestive anatomical evidence that the perivascular space (Virchow-Robin), and the ependymal cells of the ventricles and the spinal canal may participate to some degree in this process. Each blood vessel entering the nervous system is surrounded by a channel lined for a distance, varying with the caliber of the vessel, with mesothelial cells. The perivascular spaces were at one time thought to be connected with the lymphatic system but there is no evidence for this. The spaces can be traced along the blood vessels until a direct communication with nerve cells is demonstrated. This large perivascular area provides a means of communication for fluid between the subarachnoid space and nervous tissue.

Circulation

The fluid formed in the lateral ventricles passes through the foramen of Monro to join that produced in the third ventricle and thence through the aqueduct of Sylvius to the fourth ventricle. There is little doubt that the foramina in the roof of the fourth ventricle are true openings and not artefacts. The central one is the foramen of Magendie and the lateral openings bear the name of Luschka. Through these channels the fluid passes into the subarachnoid space and reaches the large *cisterna magna* dilatation (*cisterna magna*) which is situated at the medial cerebello-bulbar angle. From this *cisterna* the fluid passes slowly down the spinal canal with the arachnoid membrane and then, with some loss due to absorption and some gain due to formation in the cells lining the channel it returns to the cerebral subarachnoid space. The circulation upwards from the *cisterna magna* is somewhat more rapid and the fluid bathes the base of the brain, the cerebral hemispheres, and indeed the whole central nervous system (see fig. 387).

Absorption

When a readily diffusible dye is introduced into the subarachnoid space its rapid appearance in the blood of the venous sinuses under certain conditions demonstrates a possible path of absorption of the fluid. When the dye is injected into the cisterna magna and the spinal canal is blocked the absorption is not significantly lessened. This indicates that the fluid is largely absorbed from the cranial subarachnoid spaces. Key and Retzius believed that the fluid was absorbed through the Pacchionian granulations but these are absent from the brains of infants and are now regarded as pathological enlargements of a few of the arachnoid villi. By long-continued slow injection of an isotonic solution of a mixture of potassium ferrocyanide and iron ammonium citrate, Weed was able to demonstrate that the particles of Prussian-blue formed when the tissue was subsequently fixed in acid medium, precipitated in the mesothelial cells of the tips of the arachnoid villi and within the dural sinuses into which these villi project. A relatively slow absorption by way of the perineural spaces into the lymphatic system was also demonstrated. These findings have been confirmed and it may be accepted that the main absorption of the cerebrospinal fluid is through the arachnoid villi into the great venous sinuses. The pathway postulated by Key and Retzius has therefore been established but the numerous microscopic arachnoid villi have been substituted for the Pacchionian granulations.

MECHANISM OF ABSORPTION. Since the hydrostatic pressure in the subarachnoid space is always greater than that in the dural sinuses filtration is apparently adequate to account for the flow of fluid into the venous blood stream. True solutions readily pass through the arachnoid villi, colloids more slowly, the rate depending upon the size of the molecule; particulate matter does not pass. No evidence of any secretory activity of the arachnoid villi has been obtained.

Composition and mechanism of formation

In table 82 the amounts of the components of the cerebrospinal fluid are compared with those of blood plasma. The values given were obtained from analyses of lumbar fluid, that obtained from the ventricles may be slightly different. The water content of a unit weight of spinal fluid is somewhat greater than that of blood. The question arises, how is the fluid formed? It will be apparent from the table that if certain

constituents are investigated, diffusion from the blood plasma will be sufficient to account for the findings. However, before a decision can be reached as to whether the process is one of simple diffusion or of secretion, the concentrations of all the substances on both sides of the semipermeable membrane (the chorioid plexus) must be determined. This was done by Flexner whose findings indicate that work must be done to form this fluid, i.e., that it is not merely a filtrate from blood plasma. Since the hydrostatic pressure of the capillary blood is believed to be greater than that of the spinal fluid, except under grossly abnormal

TABLE 82*
Comparisons of amounts of main constituents of blood plasma and cerebrospinal fluid

	BLOOD PLASMA	CEREBROSPINAL FLUID
	mgm. per 100 cc.	mgm. per 100 cc.
Protein.....	6300-8500	16-38
Amino acids.....	4.5-9	1.5-3
Creatinine.....	0.7-2.0	0.45-2.20
Uric acid.....	2.9-6.9	0.5-2.8
Cholesterol.....	100-150	absent
Urea.....	20-42	5-39
Sugar.....	70-120	45-80
Chloride (NaCl).....	560-630	720-750
Inorganic phosphate.....	2-5	1.25-2.0
Bicarbonate (volumes per cent CO ₂).....	40-60	40-60
Hydrogen ions (pH).....	7.35-7.40	7.35-7.40
Sodium.....	325	325
Potassium.....	20	12-17
Magnesium.....	1-3	3-3.6

Lactic acid.....	10-32	8-27

* Data largely that compiled by Flexner.

conditions, this factor and the secretory power of the cells of the plexus are the two forces to be considered. Thermodynamic considerations indicate that the hydrostatic pressure difference would provide only a small fraction (about one-thirteenth) of the energy necessary. This leads to the conclusion that ultrafiltration will not account for the formation of the cerebrospinal fluid and that the cells of the chorioid plexus perform work during this process.

The amount and pressure

Accurate figures for the volume of the fluid in the various age groups are not available. The methods used to investigate the problem involve a

change of conditions which invalidate the results secured. The total volume in healthy adults has been given as approximately 130 cc. The normal rate of formation has not been established. When artificial drainage is provided very large volumes, several liters per day, may drain away. The results of the urinary excretion of dye injected into the cerebrospinal space suggest that the volume of fluid is renewed every three or four hours but this rate of formation is probably too high. In recent experiments in which precautions were taken to interfere as little as possible with normal pressure

FIG. 387. Lateral, horizontal view of the ventricular system. A, intraventricular foramina; B, foramen of Monro; C, anterior commissure; E, posterior commissure; F, pineal gland; G, aqueduct of Sylvius; H, fourth ventricle; I, (darker shadow) lateral recesses superimposed on the shadow of the fourth ventricle; J, superior posterior recess of the fourth ventricle; K, foramen of Magendie; L, tonsils of cerebellum; M, pons; N, medulla oblongata; O, anterior medullary velum; P, lingula of vermis of cerebellum; Q, posterior medullary velum; R, nodulus of vermis of cerebellum; S, lamina terminalis; T, choroid plexus and ependyma of roof of third ventricle; U, fornix; V, suprapineal recess (from Davidoff and Dyke).

conditions, Flexner and Winters found in experiments with adult cats, that approximately 12 cc. of fluid per day could be collected from a cannula fixed in the aqueduct. The pressure of the cerebrospinal fluid may be taken as 110 to 130 mm. of Ringer's for man in the recumbent position. Fluid drops at the rate of approximately one drop per second from the lumbar puncture needle. Pressure on the internal jugular vein or the rise of venous pressure produced by crying or coughing causes an increase in pressure of the fluid presumably by increasing the size of the capillary bed in the brain. If the rise in venous pressure is long maintained

there may also be retardation of the absorptive fluid.

EFFECT OF FLUID AND SALT INJECTIONS PRESSURE (WEED AND HUGHSON). When large volumes of isotonic solutions are injected intravenously there is a transient rise in venous cerebrospinal pressure. Hypotonic solutions cause a prolonged rise in fluid pressure due presumably to the passage of fluid into the brain. There is a marked and more transient rise of venous pressure.

Hypertonic solutions (30 per cent NaCl) administered intravenously, produce a fall in cerebrospinal pressure which may persist for long periods. Fluid is apparently attracted by the raised osmotic pressure of the blood from the brain substance, perivascular spaces, etc., into the blood stream. There is evidence also (Foley) that the direction of flow of the cerebrospinal fluid may be reversed. When the aqueduct of Sylvius is obstructed and intraventricular pressure is measured during injection of the hypertonic solution, a fall in pressure within the ventricles is noted. Using Weed's Prussian-blue, Foley was able to show that the dye passed from the ventricles into the capillaries of the choroid plexuses. When the aqueduct is open there is a current of fluid from the subarachnoid space into the ventricles. The phenomena are attributable to the raised osmotic pressure in the capillaries of the choroid plexuses.

Weed and Hughson's work was soon applied to the clinic. Intravenous injection of hypertonic saline has greatly facilitated brain operations by causing shrinkage of the brain and thus preventing extrusion of brain substance through trephine openings. It is obvious also that raised intracranial pressure resulting from various causes may be favorably affected, for a time at least, by the withdrawal of fluid from the brain. The raised osmotic pressure of the blood is usually produced by intravenous administration of saline but the oral route may be used (Cushing).

EFFECT OF CHANGE OF POSITION ON PRESSURE. It is important to realize that the fluid in the subarachnoid space of the brain and spinal cord may be regarded as a single column (approximately 60 mm. long in the man of medium height). There are no structures to act as valves and restrictions of flow are not sufficient appreciably to interfere with this relationship. The change in pressure produced by a change of position can largely be predicted by hydrostatic considerations when the blood pressure remains constant, but the elasticity of the dural sac varies in different individuals. The pressures in the lumbar and occipital regions are

entical when the subject is horizontal. The pressure in the lumbar region in man is approximately 10 mm. higher in the sitting than in the prone position. The pressure in the human cisterna magna in the erect posture is probably below atmospheric. Experimental data indicate that some point in mid-thoracic region has a pressure coinciding with that of the atmosphere. The further exploration of these questions gives promise of important advances in our knowledge of the hydrostatics of the cerebrospinal fluid (Weed). The hypothesis formulated by Monro and supported by Kellie (the Monro-Kellie doctrine) postulated constancy of cerebral volume, i.e., a reciprocal relationship between the volumes of blood and spinal fluid. The third substance within the dural sac, the brain cells, are usually assumed to remain of constant volume. This hypothesis has been restated by Weed and now includes an "elastic" factor which takes into consideration a component depending on the ease of vascular adjustments as well as the distensibility and collapsibility of the meningeal sac.

Function of the cerebrospinal fluid

The fluid within the elastic meningeal sac serves as a protective covering for the nerve cells. By change in its volume compensation for change in the amount of blood is effected and the contents of the cranium thus tend to remain of constant volume. There is probably considerable exchange of metabolic materials between the nerve cells and the fluid.

Ventriculograms and Encephalograms

The location of a bubble of air injected into the cerebral ventricles (encephalogram) or through a lumbar puncture can be detected by X-ray. The air should rise to the top of the column of fluid and follow change in position of the subject. Failure

to do this suggests abnormality of the communicating channels.

Lipiodol, an iodized vegetable oil, opaque to X-rays, is sometimes injected into the cisterna magna. Normally it falls to the lower region of the spinal canal but narrowing of the canal by tumor or adhesions may prevent its passage and the level of the obstruction can in this way be determined from X-ray pictures.

Hydrocephalus

A consideration of the formation, circulation and absorption of the spinal fluid leads to the assumption that hydrocephalus might be produced by (1) Increased rate of formation of fluid. A very definite increase can be produced by the administration of hypotonic solutions (Weed) but the decreased tonicity of the blood cannot be maintained long enough to permit the development of hydrocephalus. Clinically hypertrophy of the choroid plexuses might produce this condition and a suggestive case has been reported (Davis). (2) Obstruction to the passage of the fluid. An obstruction by tumor or inflammation in the right foramen of Monro, for example, would produce a right internal hydrocephalus. Blockage of the aqueduct of Sylvius would produce a bilateral internal hydrocephalus as would an obstruction in the fourth ventricle or at the foramina of Magendie and Luschka. (3) Interference with the absorption of fluid by way of the arachnoid villi. Blockage of many of these villi or interference with their function by other means may lead to an external hydrocephalus. Increased intracerebral venous pressure might produce a temporary decrease in absorption of fluid or, as Cushing has suggested, venous sinus thrombosis if this were compatible with life.

CHAPTER LXXIII

THE AUTONOMIC NERVOUS SYSTEM

(Synonyms—involuntary nervous system, vegetative nervous system)

The autonomic nervous system has been touched upon in many of its aspects in other sections of this book. There remains to be given an account of the structural plan of this system as a whole, a general summary of its functions and of the structures which it innervates. From anatomical, physiological and pharmacological viewpoints the autonomic system falls naturally into two main divisions—the *sympathetic* or *thoracolumbar outflow* and the *parasympathetic* or *craniosacral outflow* (see fig. 388).

THE SYMPATHETIC DIVISION

The cells of origin of the sympathetic division are situated in the lateral horns of the spinal cord (intermediolateral cell column) from the 8th cervical or 1st thoracic to the 2nd or 3rd lumbar segments. The axons of these cells leave the cord by the corresponding anterior nerve roots and connect with nerve cells in one or other of the outlying ganglia. The fibers arising from the spinal cells are medullated and are called *preganglionic*; those arising from cells of the ganglia are non-medullated, and are called *postganglionic*. Evidence for the existence of a higher center in the posterior region of the hypothalamus has been considered in Chapter LXVIII.

The ganglia are arranged in three systems or groups: (A) *vertebral* (or *central*), (B) *prevertebral* (or *collateral*) and (C) *terminal* (or *peripheral*).

A. THE VERTEBRAL GANGLIA AND GANGLIATED CORD

The vertebral group of ganglia lies in close relation to the vertebral bodies and consists, on each side, of a series of some 22 ganglia connected together by intervening fiber tracts to form a nodular cord extending from the base of the skull to the front of the coccyx. This is known as the *sympathetic chain* or the *gangliated cord of the sympathetic*. It will be described in sections.

The cervical part of the sympathetic chain

The cervical part of the sympathetic chain possesses three ganglia—the *superior*, *middle*

and *inferior cervical ganglia*. They are relatively large and are believed to result from the fusion of two or more smaller ganglia.

THE SUPERIOR CERVICAL GANGLION, situated below the base of the skull, is the largest of the three; the sympathetic supply to the head is derived from cells contained within it; it is probably formed by the fusion of the upper four cervical ganglia. Its branches are:

(1) THE INTERNAL CAROTID NERVE. This arises from the upper pole of the superior cervical ganglion and, passing into the cranium with the artery of the same name, forms the internal carotid and cavernous plexuses.

The *Internal Carotid Plexus*, situated on the lateral side of the internal carotid artery sends branches the following:

(a) The abducent nerve.

(b) The tympanic branch of the glossopharyngeal nerve.

(c) The sphenopalatine ganglion by way of the deep petrosal and the great superficial petrosal nerve which join to form the nerve to the pterygoid canal (Vidian nerve). Orbital branches of the sphenopalatine ganglion convey sympathetic fibers to the lacrimal gland; the soft palate, nasopharynx and pharynx receive fibers through the palatine and pharyngeal branches of the ganglion.

(d) The semilunar ganglion.

The sympathetic fibers pass through the sphenopalatine and semilunar ganglia without interruption.

The *Cavernous Plexus*, situated on the inner side of the internal carotid artery as it lies in the cavernous sinus, sends branches to the following:

(a) The oculomotor, trochlear and abducent nerves and the nasociliary branch of the ophthalmic division of the trigeminal nerve. Through the long ciliary nerves (twigs of the nasociliary nerve), sympathetic fibers are conveyed to the dilator pupillae (see also p. 1013).

(b) The ciliary ganglion, through which the sympathetic fibers pass without interruption into the short ciliary nerves. These fibers provide an additional pathway for sympathetic impulses to the dilator of the pupil.

(c) The pituitary body.

Through the communicating branches of the cavernous plexus the vessels of the eyeball and nasal mucosa are supplied with constrictor fibers, and the skin of the nose with vasoconstrictor, motor (smooth muscle) and secretory (sweat) fibers. The terminal filament

the internal carotid and cavernous plexuses are continued as delicate networks over the anterior and middle cerebral arteries to the minute vessels of the pia mater, and along the ophthalmic artery to the structures of the orbit.

(2) Branches to the UPPER FOUR CERVICAL NERVES.

(3) Twigs to the GANGLION JUGULARE AND GANGLION NODOSUM OF THE VAGUS, to the PETROUS GANG-

branches of the external carotid and supplies fibers to the vessels, sweat glands and cutaneous muscles of the face. Filaments from the plexus investing the facial artery pass to the submaxillary ganglion. The plexus on the middle meningeal artery sends fibers to the otic ganglion; these pass without interruption into the auriculotemporal nerve through which they reach the parotid gland.

FIG. 388. Showing plan of autonomic nervous system. C.G., ciliary ganglion. The celiac, inferior mesenteric and hypogastric ganglia are represented, in this order from above downwards, by the circles in the lower right portion of the diagram.

LION OF THE GLOSSOPHARYNGEAL NERVE and to the HYPOGLOSSAL NERVE.

(4) Filaments to the CAROTID SINUS and CAROTID BODY.

(5) The SUPERIOR CARDIAC NERVE to the cardiac plexuses.

(6) Branches which ramify in a plexiform manner upon the external carotid artery—the EXTERNAL CAROTID PLEXUS. This plexus is continued over the

THE MIDDLE CERVICAL GANGLION is formed presumably by the coalescence of the fifth and sixth cervical ganglia. Its branches are as follows:

(1) Branches to the *fifth and sixth cervical nerves* and thence to the blood vessels, sweat glands and cutaneous muscle within the area of distribution of these nerves.

- (2) *The middle cardiac nerve* to cardiac plexuses.
- (3) Branches which extend along the inferior thyroid artery to the *thyroid gland*.

THE INFERIOR CERVICAL GANGLION probably represents the union of the seventh and eighth cervical ganglia; it may be fused with the first thoracic ganglion. It gives off the following branches:

- (1) Branches to the *seventh and eighth cervical nerves*.
- (2) *The inferior cardiac nerve* to cardiac plexuses.
- (3) Branches which form plexuses upon the subclavian artery and its branches. Sympathetic fibers are thus carried into the cranial cavity along the vertebral artery, and over the axillary and commencement of the brachial (see also p. 232).

The thoracic, lumbar and sacral portions of the gangliated cord

The *thoracic ganglia* are 10 or 12 in number on each side. They are evenly spaced, one to each spinal segment. In the dog and cat, and in many human subjects, the first thoracic and inferior cervical ganglia are partially or completely fused to form an irregularly shaped mass, called the *stellate ganglion*. There are usually 4 *lumbar* and 4 or 5 *sacral* ganglia. The sacral portions of the two sympathetic trunks converge below and fuse upon the anterior surface of the coccyx to form a terminal swelling—the *coccygeal ganglion* or *ganglion impar*.

B. THE PREVERTEBRAL GANGLIA

These lie in the thorax abdomen and pelvis in relation to the aorta and its branches. The larger of the prevertebral ganglia are: (a) the *celiac (solar or semilunar) ganglion*, lying in relation to the origin of the celiac artery, (b) the *superior mesenteric ganglion*, situated below the origin of the superior mesenteric artery, and (c) the *inferior mesenteric ganglion*, which bears a corresponding relation to the inferior mesenteric artery; this ganglion is rarely present in man (see also p. 940).

C. THE TERMINAL GANGLIA

These consist of small collections of ganglion cells situated in close relation to the innervated organs, especially those of the pelvis, e.g., the bladder and rectum.

THE OUTFLOW OF SYMPATHETIC FIBERS FROM THE CENTRAL NERVOUS SYSTEM

It has already been pointed out that the cell giving rise to the sympathetic fibers (p. 936) is situated in the thoracic and upper lumbar segment of the cord. It is from this limited region (8th C. or 1st T. to 2nd or 3rd L. inclusive) that the sympathetic (preganglionic) fibers emerge. *This region constitutes the only outlet for sympathetic impulses.* So the term thoracolumbar outflow simply means the sympathetic division of the autonomic nervous system. The fibers emerge from the cord through the anterior root of the spinal segment in which their cell bodies are placed. In a cross section of the anterior root they appear as fine medullated fibers (2.5μ or less in diameter) intermingled with the larger, medullated, somatic (motor) fibers. They separate almost immediately, however, from the voluntary motor fibers of the anterior root and enter the corresponding ganglion of the sympathetic chain. Thus, the spinal nerves from the 8th cervical or 1st thoracic to the 2nd or 3rd lumbar, but not others, are connected each to a vertebral ganglion by a delicate white strand composed of preganglionic fibers and known as the *white ramus communicans* (plural *rami communicantes*, fig. 389 and fig. 102, p. 233). A preganglionic fiber after entering the ganglion may pursue one of three courses: (a) form synapses with cells in the ganglion which it first enters, (b) pass up or down the sympathetic trunk for some distance to terminate in a ganglion at a level higher or lower than that of the segment from which it originated. It may give off collateral branches to ganglion cells along its course. In any event, the preganglionic fibers issuing from a given segment connect with several ganglia (from five to nine). Furthermore, each preganglionic fiber may form a large number of synapses within a given ganglion. Ranson and Billingsley found that in the case of the superior cervical ganglion each fiber communicated with some twenty-two ganglion cells; this accounts for the diffuse nature of the sympathetic discharge. (c) Traverse the gangliated cord without interruption to find a cell station in either a prevertebral or a terminal ganglion.

PLAN OF DISTRIBUTION OF SYMPATHETIC FIBERS TO THE PERIPHERY

To the limbs and trunk

The ganglia of the sympathetic chain are connected with the spinal nerves supplying the

limbs and trunk by delicate filaments called *gray rami communicantes*. They are composed of the axons of the ganglion cells and are therefore called *postganglionic*. The gray rami in the thoracic and upper lumbar regions join the spinal nerves close to the points at which the white rami arise. Their constituent fibers are continued to the periphery for the supply of the blood vessels, sweat glands and smooth muscle of the skin. Whereas, as already mentioned, only a limited number of spinal nerves possess white rami,

the upper limb as well as those to the head and neck and heart. This operation may fail, however, completely to remove the sympathetic supply to the arm since a gray ramus (Kuntz's nerve) frequently passes from the second thoracic ganglion via the first thoracic nerve to join the brachial plexus.

To the head and neck

Sympathetic impulses to the structures of the neck, face, scalp and intracranial cavity are con-

FIG. 389. Diagram showing the connections of sympathetic fibers. Efferent fibers in black; preganglionic, solid lines; postganglionic, interrupted lines. Afferent visceral fiber in red.

every spinal nerve receives a gray ramus. It therefore follows that sympathetic impulses going to parts supplied by upper cervical, lower lumbar or sacral somatic nerves, must travel considerable distances up or down the sympathetic trunk before reaching an outlet through a gray ramus. The postganglionic fibers to the upper limb arise from the first thoracic, and the inferior and middle cervical ganglia; those for the lower limb from the lumbar and sacral ganglia. Excision of the stellate ganglion (inferior cervical and first thoracic) interrupts the sympathetic pathways to

veyed from the cord in the white rami of the upper two thoracic nerves. They ascend to connect with cells in the middle and superior cervical ganglia. From the latter postganglionic fibers are distributed through the internal carotid, cavernous and external carotid plexuses as described on page 936. The sympathetic as well as supplying the blood vessels, sweat glands and pilomotor muscles of the head and neck also innervates the salivary glands, the dilator pupillae, Mueller's muscle and the smooth muscle component of the levator palpebrae superioris. Sympathetic fibers

also descend the infundibular stalk to the pituitary gland. The spinal center for the dilator pupillae is situated (in man) in the 8th cervical segment.

To the thoracic viscera

The sympathetic postganglionic fibers join with the branches from the vagus to form the *cardiac*, *pulmonary* and *esophageal plexuses*.

The *cardiac plexus* lies in relation to the origins of the aorta and pulmonary artery. It consists of a superficial and a deep portion, and is formed by the interlacement of fibers from the cardiac branches of the vagus (parasympathetic) and sympathetic nerves. The vagus fibers are preganglionic. They terminate around ganglion cells in the walls of the heart (p. 205). The sympathetic fibers derived from the superior, middle and inferior cardiac nerves are postganglionic, their cell stations lying in the corresponding cervical ganglia (fig. 95, p. 207). The preganglionic fibers arise from the upper four or five thoracic segments of the cord.

The *pulmonary plexuses*, anterior and posterior, lie in relation to the corresponding aspects of the root of the lung. They are formed from postganglionic fibers of the sympathetic (T. 2, 3 and 4) and preganglionic fibers of the vagus. The latter connect with ganglion cells in the walls of the bronchi. Herein is situated an intrinsic nervous plexus consisting of these ganglion cells and medullated and non-medullated fibers.

The *esophageal plexus* embraces the lower half of the esophagus. Vagal and sympathetic fibers (from the upper thoracic ganglia and from the thoracic portion of the great splanchnic nerve) enter into its formation. The vagal fibers end around ganglion cells of the intrinsic plexus of Auerbach in the esophageal wall.

To the abdominal and pelvic viscera

The *greater, lesser and least splanchnic nerves*. These are composed of preganglionic fibers, and may be looked upon as elongated white rami. They connect with cells in the prevertebral (collateral) ganglia. The postganglionic fibers after emerging from the latter join the neighboring plexuses. The *greater splanchnic* nerve arises from the cord from as high as the 4th or 5th thoracic segment, and as low as the 9th or 10th. Its fibers end in the upper part of the celiac ganglion; from here postganglionic fibers are continued into the celiac plexus. The *lesser splanchnic* and the *least (or lowest) splanchnic* nerves are much smaller.

The former arises from the 10th and 11th thoracic segments and its fibers, after passing without interruption through the vertebral ganglia at these levels, end in the lower portion of the celiac ganglion. The least splanchnic nerve arises from the last one or two thoracic segments and first lumbar segment; it joins the renal plexus (fig. 390).

The *lumbar splanchnic nerves* are three or four strands which arise from the second and third lumbar segments. Their fibers pass through the lumbar portion of the sympathetic chain and enter the inferior mesenteric ganglion; here some are relayed, others are continued without interruption and find their cell stations in peripheral ganglia.

THE PLEXUSES OF THE ABDOMEN AND PELVIS. The sympathetic fibers form rich plexuses in relation to the aorta and its branches from which filaments pass to the abdominal and pelvic viscera. Parasympathetic fibers also enter into the constitution of these plexuses.

The *celiac (or solar) plexus* lies upon the abdominal aorta at the origin of the celiac artery. The *celiac ganglia*, right and left, lie embedded within the plexus, which is made up of fibers arising in the ganglion (i.e., postganglionic fibers of the greater and lesser splanchnic nerves) together with preganglionic fibers of the vagus. The lower part of the celiac ganglion is often detached and is then referred to as the *aorticorenal ganglion*. The plexus invests the celiac artery throughout its course and gives rise to several subordinate plexuses—the *hepatic, gastric, splenic, renal* and *adrenal plexuses*—which invest the corresponding arteries and their branches.

The *superior mesenteric plexus* is continuous above with the celiac plexus. It surrounds the superior mesenteric artery, along the branches of which it is prolonged. The plexus is composed of postganglionic fibers which arise in an aggregation of nerve cells—the *superior mesenteric ganglion*—lying within it, and of preganglionic fibers derived from the lumbar segments of the cord. The superior mesenteric plexus supplies the pancreas, and the small intestine and the large intestines as far as the commencement of the descending colon.

The *aortic or intermesenteric plexus* lies upon the aorta between the origins of the superior and inferior mesenteric arteries. It receives fibers from the celiac plexus and from the upper lumbar ganglia. The aortic plexus gives rise secondarily to the *spermatic* and *ovarian plexuses* which supply the testes and ovary with autonomic fibers. It is connected below with the *inferior mesenteric plexus* which invests the artery of the same name. The *inferior mesenteric ganglion*, a collection of ganglion cells lying within the latter plexus, receives the lumbar splanchnics; this ganglion is not present,

as a rule, in the human subject (Learmonth). The plexus is formed of fibers derived from the aortic plexus and from the inferior mesenteric ganglion when this is present. From it secondary plexuses arise which invest the branches of the inferior mesenteric artery and carry sympathetic impulses to the descending colon, iliac colon, pelvic colon and rectum.

among which are scattered numerous small ganglia which are sometimes referred to collectively as the *hypogastric ganglion*. Parasympathetic fibers enter the inferior hypogastric plexuses through the pelvic nerve (sacral outflow, p. 842). The sympathetic fibers contributing to the pelvic plexuses have their ultimate source in the lumbar segments of the cord.

FIG. 390. Diagram of the nerve plexuses of the abdomen and pelvis. A.R., aortico-renal.

The *superior hypogastric plexus* is the downward extension of the aortic plexus. It lies in the angle formed by the bifurcation of the aorta. Though rarely condensed into a single bundle it is sometimes referred to as the *hypogastric nerve* or the *presacral nerve*. It transmits inhibitory impulses to the pelvic colon and via the pelvic plexuses to the rectum, bladder and other pelvic viscera. It divides below into the right and left *pelvic* or *inferior hypogastric plexuses*. These lie one on either side of the rectum and are composed of medullated and non-medullated fibers

They reach the plexuses via the hypogastric plexuses as well as more directly from the sacral part of the sympathetic chain. Through subsidiary plexuses—*hemorrhoidal, vesical, uterine, vaginal* and *prostatic*—fibers (sympathetic and parasympathetic) are conveyed from the pelvic plexuses to the pelvic viscera.

THE PARASYMPATHETIC OR CRANIOSACRAL DIVISION

The cells giving rise to parasympathetic fibers are situated at three different levels of the central nervous system—the *mid-brain*, the *medulla*

and the *sacral region of the spinal cord*. The axons of these cells leave the central nervous system to connect with ganglion cells lying within or in close relation to the innervated organ (see fig. 388). As in the case of the sympathetic division the axons of the central cells are called *preganglionic*; those of the ganglion cells, *postganglionic*. The former are medullated, the latter non-medullated.

The three levels from which parasympathetic fibers emerge will be referred to as the *tectal* (or *mid-brain*), the *bulbar* and the *sacral* outflows, respectively.

A. THE TECTAL OR MID-BRAIN OUTFLOW

The group of cells composing the Edinger-Westphal nucleus of the oculomotor nerve (p. 1016) are believed to give rise to the tectal fibers.

The autonomic fibers are conveyed in the third nerve as far as the ciliary ganglion where they find their cell stations. Postganglionic fibers emerge from the ganglion in the short ciliary nerves, and terminate in the sphincter pupillae and the ciliary muscle (p. 1012).

B. THE BULBAR OUTFLOW

These fibers leave the brain in the *facial*, *glossopharyngeal* and *vagus nerves*.

(1) The parasympathetic fibers (secretory and vasodilator) entering the *facial nerve* arise from the *superior salivary nucleus*, which lies dorsal and lateral to the lower end of the motor nucleus of the facial. These fibers emerge from the brain in the sensory root of the facial nerve (*nervus intermedius*, p. 859) and travel with the latter to the facial canal of the temporal bone. Here they leave the facial, (i) in its *chorda tympani* branch which later joins the lingual to be conveyed to the floor of the mouth. At this point some of the chorda fibers (secretory and vasodilator in function) separate from the lingual again to enter the submaxillary gland where they synapse with ganglion cells; other secretory and vasodilator fibers of the chorda tympani nerve proceed to the *submaxillary ganglion* from which postganglionic fibers pass to the sublingual gland (p. 417); (ii) in the great superficial petrosal nerve and nerve of the pterygoid canal (Vidian nerve) to the sphenopalatine ganglion. From here postganglionic fibers pass via orbital branches of the ganglion to the lacrymal gland, and to the mucous membrane of the soft palate, nasopharynx and pharynx via the palatine nerves.

(2) The parasympathetic fibers (secretory and vasodilator) of the *glossopharyngeal nerve* arise from cells of the *inferior salivary nucleus*. This nucleus lies below the superior salivary nucleus, and lateral to the motor nucleus of the glossopharyngeal nerve. The autonomic fibers leave the brain with the latter nerve but separate

from it again in its tympanic branch. The latter joins a branch of the genicular ganglion of the facial to form the small superficial petrosal nerve; the parasympathetic fibers are continued in the small superficial petrosal nerve to the otic ganglion from where postganglionic fibers are conveyed to the parotid gland via the auriculotemporal nerve (fig. 183, p. 418).

(3) The *vagus nerve* contains the greater proportion of the fibers of the bulbar outflow. They arise from the *dorsal nucleus* of the vagus and are distributed through the latter's numerous branches to the thoracic and abdominal viscera (p. 861). Unlike those in the other two cranial nerves, the preganglionic fibers of the vagus connect with ganglion cells situated within the innervated organs. Thus the vagal fibers to the heart connect with ganglion cells in the cardiac wall; those to the bronchi with the nerve cells of the intrinsic plexus in the bronchial walls; those to the esophagus, stomach and intestine form synapses with the ganglion cells of the myenteric plexus of Auerbach and the submucous plexus of Meissner. The preganglionic fibers are therefore quite long, the postganglionic very short.

C. THE SACRAL OUTFLOW

The cells of origin lie in the anterior horns of the 2nd, 3rd and 4th and sometimes the 1st sacral segments of the cord. The preganglionic fibers emerge in the anterior roots of the corresponding sacral nerves. The fibers leave the spinal nerves again and, proceeding peripherally as the *pelvic nerve* (or *nervus erigens*), on each side, enter into the formation of the pelvic plexus (p. 941). The fibers terminate around ganglion cells lying in close relation to the pelvic organs. They carry motor impulses to the walls of the descending colon, rectum and bladder; inhibitory impulses to the internal anal and vesical sphincters and to the uterus; and dilator impulses to the blood vessels of the bladder, rectum and genitalia.

THE AFFERENT VISCERAL NERVES

Impulses are transmitted from the viscera by afferent fibers which pass through the various plexuses and reach the central nervous system via the vagus, pelvic, splanchnics and other autonomic nerves. The *afferent fibers of the vagus* are the peripheral processes of cells in the ganglion jugulare and the ganglion nodosum. The central processes of these neurons terminate in the dorsal nucleus of the vagus (p. 861). Therein connections are made with efferent parasympathetic neurons to complete the reflex arc. The *afferent fibers of the pelvic nerve* arise from cells in the posterior root ganglia of the 2nd, 3rd and 4th sacral nerves. They pass peripherally with the

fferent autonomic fibers. The *afferent fibers of the sympathetic division* are the peripheral processes of ganglion cells in the posterior spinal nerve roots from the 1st thoracic to the 3rd lumbar segments. *None arise from sympathetic ganglia.* They reach the sympathetic trunk via the white rami communicantes and are distributed to the viscera along with the corresponding efferent fibers (fig. 389). Though some of these afferent fibers are non-medullated the majority are medullated, and of larger size than the efferent fibers. The ganglion cells of the posterior roots which give origin to the afferent fibers of the sympathetic (or of the pelvic nerve) have not been shown definitely to differ from those giving rise to the ordinary somatic sensory fibers. For this reason the sympathetic system proper is regarded as consisting solely of efferent neurons. The afferent fibers pass to their destinations without interruption in any of the sympathetic ganglia, passing directly to the viscera in the splanchnics or other visceral efferents. A certain proportion also enter the spinal nerves for distribution to the limbs via the gray rami.

The visceral reflex arc

The visceral reflex arc, as pointed out by Gaskell, is formed upon a plan similar to that upon which somatic reflexes are based. The afferent fiber in the latter instance is connected to the anterior horn cell through the intermediary of an intraspinal neuron or a series of such neurons. These are spoken of as connector neurons. In the case of visceral reflexes, the afferent fiber makes contact with a cell in the lateral horn of gray matter. The axon of this cell—the preganglionic fiber—which connects with a ganglion cell of the sympathetic system, corresponds to the connector fiber of the somatic reflex arc. In development, however, this neuron has migrated from the central nervous system, being only in part intraspinal. The neuron with which it communicates, i.e., the ganglion cell and postganglionic fiber, though it has been carried entirely beyond the bounds of the central nervous system, corresponds to the motor neuron of the somatic reflex arc.

A certain degree of independent reflex activity can be carried out through the intrinsic plexuses, e.g., of the intestine, when these are separated from the central nervous system by division of the main autonomic nerves. It is also true that some independent activity can be carried out through axon reflexes or possibly through some of the more peripherally placed ganglion cells. Other parts of the autonomic system, however,

cannot function apart from the central nervous system. The larger ganglia of the parasympathetic or sympathetic, for instance, do not serve as reflex centers. It is clear from the description of the origin and course of the visceral afferent nerves given above that no anatomical basis for such action exists.

THE FUNCTIONS OF THE AUTONOMIC NERVOUS SYSTEM

The autonomic nervous system governs the activities of cardiac and smooth muscle, of the digestive glands and sweat glands, and of certain endocrine organs. It is concerned with those processes which normally are beyond voluntary control and are for the most part beneath consciousness. The term autonomic as applied to the system is not altogether suitable since, as we have seen, it is under the control of centers within the central nervous system, and cannot function as an independent unit.

Through its various activities the autonomic system exercises the important function of maintaining the constancy of the fluid environment of the body's cells; it serves to combat forces, acting either from within or without, which tend to cause variations in this environment. Regulation of the composition of the body fluids, of their temperature, quantity and distribution is effected through the actions of the autonomic nerves upon circulatory, respiratory, excretory and glandular organs. For example, of glandular structures under autonomic influence, the liver, pancreas and adrenal are of especial importance in the regulation of blood sugar; the sweat glands aid in the control of body temperature. The pituitary gland in some of its functions, at least, is also under autonomic control. The thyroid and probably the parathyroids are governed in turn by hormones liberated by the pituitary (p. 725); though it is not improbable that they may be influenced also by impulses received through autonomic paths. The stability of the internal environment (the *milieu interne* of Claude Bernard) which is so characteristic of the healthy body, is spoken of by Cannon as *homeostasis*. According to Cannon, the essential and particular function of the autonomic system is to bring about the internal adjustments upon which this constant state depends. He therefore refers to the autonomic nerves as the *interofective* system. He speaks of the voluntary system (i.e., the central nervous system and the somatic nerves) as the *exteroffective* system, since through its exteroceptors and

TABLE 83

ORGAN	PARASYMPATHETIC EFFECTS*	ORIGIN OF SYMPATHETIC POSTGANGLIONIC FIBERS	SYMPATHETIC EFFECT
<i>Heart</i> (p. 205, 207)	Inhibition	Superior middle and inferior cervical ganglia	Acceleration
<i>Vessels:</i>			
Cutaneous (p. 232-234)	—	Various vertebral ganglia	Constriction
Muscular (p. 234)	—	Various vertebral ganglia	Dilatation, Const.
Coronary (p. 278)	Constriction	Cervical ganglia	Dilatation
Salivary glands (p. 417)	Dilatation	Superior cervical ganglion	Constriction
Buccal mucosa	—	Superior cervical ganglion	Dilatation
Pulmonary (p. 284)	Dilatation and constriction	Thoracic vertebral ganglia	Constriction and dilatation
Cerebral (p. 290)	Dilatation	Superior cervical ganglion	Constriction
Abdominal and pelvic viscera (p. 940)	—	Prevertebral ganglia	Constriction
External genitalia (p. 236)	Dilatation	Prevertebral ganglia	Constriction
<i>Eye:</i>			
Iris (p. 1012)	Constriction	Superior cervical ganglion	Dilatation
Ciliary muscle (p. 1016)	Contraction	Superior cervical ganglion	Relaxation
Smooth muscle of orbit and upper lid (p. 1016)	—	Superior cervical ganglion	Contraction
Nictitating membrane (cat and dog)	—	Superior cervical ganglion	Retraction
<i>Bronchi</i>	Constriction	Thoracic ganglia	Dilatation
<i>Glands:</i>

Islets	Secretion	Celiac ganglion	—
Liver (p. 592)	—	Celiac ganglion	Glycogenolysis
Adrenal (p. 684) medulla	—	No postganglionic fibers	Secretion
<i>Smooth muscle:</i>			
Of skin	—	Vertebral ganglia	Contraction
Of stomach wall (p. 488)	Contraction or inhibition	Celiac ganglion	Contraction or inhibition
Of small intestine (p. 501)	Increased tone and motility	Celiac and superior mesenteric ganglia	Inhibition
Of large intestine (p. 502)	Increased tone and motility	Inferior mesenteric and hypogastric ganglia	Inhibition
Of bladder wall (p. 413) (detrusor muscle)	Contraction	Inferior mesenteric and hypogastric ganglia	Inhibition
Of trigone and sphincter	Inhibition	Inferior mesenteric and hypogastric ganglia	Contraction
Of uterus, pregnant		Inferior mesenteric and hypogastric ganglia	Contraction
Of uterus, non-pregnant			Inhibition

* With certain exceptions, e.g., those supplying the sublingual and parotid glands and the sphincter pupillae the postganglionic fibers of the parasympathetic arise from cells situated in, or in close proximity to, the innervated organ itself.

effectors a direct relationship is established with the external environment.

The great majority of the effector organs of the autonomic system are innervated by both sym-

pathetic and parasympathetic divisions (see table 83), and the effects exerted by the two types of fiber going to a given organ are antagonistic. Thus the heart's action is inhibited by the vagus

but augmented by the sympathetic (p. 207). In the intestine the effects of the two nerves are reversed, the parasympathetic (vagus nerve to the small bowel, pelvic nerve to the large) is augmentor; the sympathetic inhibitory. The removal of the effects of one set of fibers, as by section, results, as a rule, in the effects of the other set becoming more prominent. This fact indicates that each type of fiber exerts a constant or tonic action and suggests that the two effects are delicately balanced one against the other. Thus, section of the vagus nerves causes an increase in the cardiac rate, and section of the parasympathetic or of the sympathetic fibers to the iris causes, respectively, dilatation or constriction of the pupil. See pupillary reactions, p. 1011.

Taken as a whole the actions of the sympathetic division and its ally the adrenal gland (sympathoadrenal system, p. 690) are directed towards strengthening an animal's defences against the various dangers which beset it, e.g., extremes of temperature, deprivation of water or the attacks of its enemies. It has been shown by Cannon, however, that the sympathetic system is not indispensable; both gangliated cords may be completely removed yet the animal remains in good health provided it is kept in the sheltered environment of the laboratory. Sympathectomized cats if kept warm and carefully tended will live indefinitely. Kittens deprived of their sympathetic trunks grow normally, female cats become pregnant and give birth to young, though the mammary glands do not function and the maternal instinct is lacking. Sympathectomized animals are, however, incapable of arduous work, sugar is not mobilized from the liver on demand, an increase of circulating red cells does not occur during excitement or exercise (p. 54), the usual reactions to cold (elevation of the hairs and vasoconstriction) fail, and adrenaline is not liberated in an emergency. They are also less able to withstand oxygen lack or hemorrhage than are normal animals. It is evident that the sympathectomized animal could not fend for itself, and, in the struggle for existence, would soon succumb to the hazards of the environment.

Parasympathetic effects, rather than being characterized by a diffuse outburst of activity, as may result from sympathetic stimulation, are more localized in character. It has also been suggested that they are concerned with conservative and restorative processes, and the sympathetic with processes involving the expenditure of energy.

Inhibition of the heart, contraction of the pupil for the protection of the eye from intense light and the activities of the digestive tract, through which the energy stores of the body are replenished, are frequently given as examples of acts of conservation presided over by the parasympathetic. These apparent differences in the activities of the two divisions have led some to speak of the functions of the sympathetic and parasympathetic divisions as *catabolic* and *anabolic*, respectively. It is an interesting but perhaps a too speculative generalization.

A summary of the actions of the autonomic system upon various structures is given in table 83.

THE ACTIONS OF CERTAIN DRUGS UPON THE AUTONOMIC SYSTEM

NICOTINE paralyzes ganglion cells or the junction (synapse) between the cell and the pre-ganglionic fiber. The fibers themselves remain unaffected by the drug. An excitatory effect precedes the paralysis. The power of nicotine to paralyze ganglion cells renders it a most valuable means of locating the ganglion cells of autonomic nerves. If, for example, after a certain ganglion has been painted with the drug, stimulation of the fibers on the proximal side of the ganglion fails to cause the customary response, then it is concluded that the fibers in question have their cell stations in the treated ganglion. Nicotine also causes the contraction of striated bird and frog muscle and of denervated mammalian muscle. This excitatory effect is abolished by an excess of nicotine.

ADRENALINE (p. 685) acts upon structures innervated by the sympathetic. The sweat glands of most animals are an exception. Denervation of the effector organ sensitizes it to the action of adrenaline (p. 947).

ERGOTOXINE AND ERGOTAMINE paralyze motor and secretory fibers of the sympathetic but not the inhibitory fibers. When injected intravenously into the conscious animal (cat) ergotoxine produces a condition of "sham rage" (p. 884).

PILOCARPINE causes parasympathetic effects, e.g., cardiac inhibition, contraction of the smooth muscle of the eye, bronchioles and alimentary tract, and secretion from the salivary, bronchial and gastric glands. *It also stimulates the sweat glands* which receive excitatory fibers from the sympathetic. The action of pilocarpine like that of muscarine or of acetylcholine is directly upon the effector cell.

MUSCARINE acts similarly to pilocarpine upon the heart and the smooth muscle of the alimentary tract, bladder and bronchioles. It constricts the pupil, and stimulates the salivary glands and sweat glands. It also causes vasodilatation.

CHOLINE AND ITS ESTER, ACETYLCHOLINE imitate closely the effects of parasympathetic stimulation, causing cardiac inhibition, excitation of the smooth muscle of the digestive tract and bladder wall, and the secretion of saliva, tears and sweat. It causes in addition dilatation of the arterioles and a fall in blood pressure. Acetylcholine is some 1000 times more powerful than choline itself. One part in many millions causes inhibition of the perfused frog's heart or contraction of an isolated intestinal segment. The ester is rapidly hydrolyzed in alkaline media into acetic acid and choline, and blood and other body fluids contain an enzyme—*cholinesterase*—which rapidly inactivates it. The action of the esterase is inhibited by physostigmine. This drug, therefore, by preventing the destruction of acetylcholine by the body fluids, greatly intensifies its action. In addition to the parasympathetic effects of acetylcholine, which have been termed its "muscarine" action, it has a stimulant action upon ganglion cells, upon the muscles of the body wall of the leech, upon voluntary frog muscle and upon denervated mammalian muscle. These effects of acetylcholine resemble those caused by nicotine and are referred to as its "nicotine" action. The latter, unlike the "muscarine" action, is not annulled by atropine but is abolished by a large dose of nicotine and by curarine.

PHYSOSTIGMINE OR ESERINE is identical in its action with acetylcholine. As just mentioned, it acts simply by inhibiting the action of the choline esterase, and so permitting the cholinester liberated at the nerve endings to exert its full effect.

ATROPINE annuls parasympathetic effects, and antagonizes the actions of pilocarpine, of muscarine and of the "muscarine" action of acetylcholine. It is believed to act directly upon the effector cell, preventing the action but not the liberation of acetylcholine. It therefore quickens the heart, and paralyzes the sphincter pupillae and ciliary muscles and thus causes pupillary dilatation and failure of accommodation. It suppresses the secretion of saliva, and of the nasal, bronchial and gastric glands. It is inhibitory to the bronchial muscles and lowers the tone of the intestinal musculature. *It also suppresses the secretion of the sweat glands which are innervated by the sympathetic (see p. 948).*

THE CHEMICAL TRANSMISSION OF NERVOUS EFFECTS TO AUTONOMIC EFFECTORS AND SKELETAL MUSCLE

Within the past few years evidence has accumulated which clearly indicates that parasympathetic effects are mediated through a chemical substance liberated at the nerve terminals. This substance is identical in its action with acetylcholine. Experiment has also shown that certain sympathetic endings liberate an adrenaline-like substance (sympathin). Acetylcholine also serves as a chemical transmitter of certain sympathetic effects.

Space does not permit an extended account of the experimental work upon which present day knowledge of these humoral mechanisms is based, but a summary of the more important facts will be attempted. The work of Loewi upon the transmission of cardiac effects (vagal and accelerator) and Cannon's discovery of "sympathin" (p. 691) have already been considered.¹

The experiments to be described involve either (a) a comparison of the effects of autonomic and motor nerve stimulation with the pharmacological actions of acetylcholine or, (b) the stimulation of the autonomic nerves to an organ, e.g., the salivary gland, and testing the venous blood issuing from it, or the fluid with which it has been perfused, for an acetylcholine-like action. In order to prevent the hydrolysis by cholinesterase of acetylcholine after its liberation from the nerve terminals, eserine in a dilution of 1 in 1 million or so is added to the perfusion fluid. The following is a list of the tests employed and the pharmacological effects which indicate the presence of acetylcholine.

(1) *Blood pressure of the cat.* Dilatation of the arterioles and a fall in blood pressure ("muscarine" action). The effect should be annulled by atropine. (2) *Inhibition of the perfused frog's heart or rabbit's auricle* ("muscarine" action annulled by atropine). (3) *Contraction of the voluntary muscle (rectus abdominis) of the frog* ("nicotine" action). (4) *Contraction of the muscle in body wall of the eserinated leech* ("nicotine" action). This test is sensitive to 2 gamma of acetylcholine per liter. (5) The active substance should be inactivated by alkali or by uneserinated blood (which contains cholinesterase).

During nerve stimulation the acetylcholine-

¹ The suggestion that a chemical substance might be liberated from nerve endings was made by Elliott (1904-5), and before him by Du Bois-Reymond, though no direct experimental evidence was offered.

like substance is liberated and enters the blood or perfusion fluid in such minute amounts that its chemical identification is out of the question. Had acetylcholine not been demonstrated by chemical analysis to be a normal constituent of the body, such purely pharmacological tests for its appearance during nerve stimulation would still leave some doubt that it was actually the substance concerned. This doubt was removed by the work of Dale and Dudley who obtained chemically recognizable amounts of this choline ester from the spleen of the horse. It is also present in human placenta and in nervous tissues; only minute amounts are present in blood. That the chemical mediator is actually acetylcholine is now generally accepted. With one exception (namely pyruvylcholine) no choline ester other than acetylcholine has an action quantitatively comparable with that exhibited by the chemical transmitter. Moreover, acetylcholine is the only ester of choline found in animal tissues.

Summary of experimental work relating to the rôle played by acetylcholine in the transmission of nervous effects

(1) *Stimulation of the chorda tympani to salivary glands.* Babkin and his associates found that when the chorda of one side was stimulated a substance entered the blood which caused a fall in blood pressure and secretion from the denervated salivary gland of the opposite side. These effects were abolished by atropine. Similar results have been obtained by others. During stimulation of the chorda of a perfused salivary gland, for example, a substance identical in action with acetylcholine was found by Henderson and Roepke in the perfusion fluid.

(2) *The liberation of acetylcholine from parasympathetic endings in the iris.* When a strong light was thrown into one eye, the other eye being shaded, an acetylcholine-like substance was obtained from the aqueous humor of the illuminated eye but not from the darkened eye (Engelhart).

(3) *Acetylcholine and vasodilator nerves. The hypersensitivity of denervated structures to chemical stimulation.* Many years ago Philipeaux and Vulpian (1863) observed that after section and degeneration of the hypoglossal nerve, stimulation of the chorda tympani going to the tongue caused a peculiar slow and prolonged contraction of the lingual muscles (Vulpian effect) and vasodilatation. Stimulation of the chorda causes no effect upon the normal tongue other than vasodilatation. Acetylcholine also causes this peculiar contraction of the denervated tongue muscles ("nicotine" action) together with vasodilatation ("muscarine" action). It has therefore been suggested that the vasodilatation following chorda stimulation is due to the liberation of acetylcholine from the nerve ter-

minals, and that the Vulpian effect results from the diffusion of the active substance to the muscle fibers rendered sensitive by denervation. A reaction analogous to the Vulpian effect was described by Sherrington, who found that after the muscles of the leg were deprived of their *motor* innervation by sectioning the ventral roots containing fibers for the sciatic nerve, and allowing time for the degeneration of the fibers to occur, stimulation of the sciatic caused the characteristic slow contraction of the muscles. The effect can be duplicated by acetylcholine. Evidence was subsequently obtained which indicated that the nerve fibers concerned ended upon the blood vessels. It was therefore concluded that the effect was due to the liberation of acetylcholine from the sensory fibers which normally carried antidromic vasodilator impulses (p. 235). It now appears, however, from the work of Hinsey and Cutting, that *sympathetic* postganglionic fibers arising from the lumbar and sacral ganglia and reaching the sciatic nerve via the gray rami are responsible. This leads to the suggestion that acetylcholine liberation from *sympathetic* terminals upon the blood vessels causes vasodilatation and the Sherrington phenomenon as a secondary effect due to diffusion of the ester from its site of production to the muscle fibers. The latter as well as the Vulpian effect is intensified by eserine. An effect of the same nature as the Sherrington phenomenon is obtained upon stimulation of the cervical sympathetic after section and degeneration of the facial nerve, viz., dilatation of the vessels of the gums and lips together with contraction of the muscles of the upper lip (Rogowitz).

Another example of increased sensitivity of denervated muscle to acetylcholine is the interesting and suggestive observation made more recently by Bender. After section and degeneration of the 7th nerve in monkeys the denervated facial muscles were found to contract involuntarily when the animal became angry or frightened. This "*fright reaction*" can be duplicated by the injection of acetylcholine and is accentuated by eserine. It is attributed to the release of acetylcholine into the general circulation from some unknown source. The phenomenon recalls the liberation of adrenaline in emotional states and the hypersensitivity to adrenaline or sympathin of the denervated iris. Further examples of the hypersensitivity of denervated structures to acetylcholine, adrenaline and other chemical agents can be cited, e.g., the greater secretory response of the denervated salivary gland to pilocarpine, the hypersensitivity of the pupil to acetylcholine after section of the 3rd nerve and of the nictitating membrane to adrenaline following excision of the superior cervical ganglion. The inhibitory effects of adrenaline (e.g., on the bowel and non-pregnant uterus) are also enhanced by denervation. These and other similar observations have led to the formulation by Cannon of a *law of denervation* which he states in the following terms: "When in a series of efferent neurons a unit is destroyed, increased irritability to chemical

agents develops in the isolated structure or structures, the effect being maximal in the part directly denervated."

If the effects described in the first paragraph of this subsection are actually due to acetylcholine one would expect the vasodilatation ("muscarine" action) to be prevented by atropine. But this is not the case. Though atropine annuls the vasodilator action of acetylcholine it does not prevent the effects of stimulating vasodilator nerves. It has been suggested (Dale), in an effort to explain this discordant fact, that acetylcholine is liberated in such intimate relation to the smooth muscle of the vessel that atropine fails to reach it.

(4) *Acetylcholine as an intermediary of parasympathetic effects to the alimentary tract and bladder.* It has been shown that Ringer's solution in which a beating loop of intestine is immersed is capable of augmenting the activity of another similar loop (Weiland). It has also been found that if the vagus nerve to the intestine is stimulated and a loop then removed and suspended in Ringer's solution, the contractions of this loop are greater than those of a similar one which had not been previously excited in this manner. These experiments suggest that during intestinal activity a substance is liberated by the vagal endings which has an augmenting effect upon the contractions. Evidence for the liberation of acetylcholine by the gastric vagus has recently been obtained by Dale and Feldberg. A substance identical in action with acetylcholine was detected in the venous blood leaving the resting stomach or in the eserinizd fluid perfusing its wall. During vagal stimulation the quantity of the active material was increased four-fold.

An acetylcholine-like substance has also been identified by Henderson and Roepke in the fluid perfusing the bladder during stimulation of its parasympathetic nerves. In the case of the intestine and bladder as in the case of vasodilator nerves, the same discrepancy exists between the action of atropine upon the effects of nerve stimulation and the action of the drug upon the effects of acetylcholine administration. Atropine abolishes the action of acetylcholine when applied artificially to these organs but does not depress the contractions set up by parasympathetic stimulation. Henderson and Roepke conclude from the results of their experiments that, whereas the tone of the intestine and of the bladder is dependent upon the liberation of a choline ester, another mechanism is responsible for the phasic contractions. Atropine, as is well known, depresses the tone of the intestinal and vesical musculatures but exerts no direct effect upon the contractile mechanism.

(5) *The liberation of acetylcholine from sympathetic preganglionic fibers.* Feldberg and Gaddum perfused the superior cervical ganglion with eserinizd fluid. The inflow cannula was inserted into the common carotid artery, all branches of which had been tied except the one to the ganglion. The fluid was collected

from the internal jugular vein, all its tributaries except that from the ganglion having been occluded. During stimulation of the cervical sympathetic trunk below the ganglion the fluid issuing from the vein was found to possess an action identical with that of acetylcholine. When the collected fluid was passed through the ganglion of the opposite side its stimulant action ("nicotine" action) upon this structure was evidenced by a contraction of the nictitating membrane. Fluid collected before or after the period of stimulation showed no such activity.

(6) *Acetylcholine liberation during the discharge of adrenaline.* Stimulation of the sympathetic fiber supplying the adrenal medulla causes an acetylcholine like substance to appear in the blood of the adrenal vein. It has therefore been concluded that acetylcholine acts as a chemical transmitter from the nerve terminals to the medullary cells. It will be recalled that the sympathetic fibers ending in the adrenal are preganglionic, the adrenal cell itself taking the place of the ganglion cell (p. 684). It is mainly the "nicotine" action of acetylcholine (i.e., abolished by a large dose of nicotine but not by atropine) which is exerted upon the adrenal, but there is also a slight "muscarine" action.

(7) *Acetylcholine as the transmitter of effects to the sweat glands.* Though the human sweat glands are innervated by the sympathetic their behavior to drugs is similar to that of structures supplied by the parasympathetic; they are unaffected by adrenaline, stimulated by pilocarpine, and paralyzed by atropine. An experiment of Dale and Feldberg gives an explanation of these discrepancies, or at any rate brings the mechanism of sweat secretion into the general scheme. Excitation of the sympathetic fibers to the foot pads of the cat was followed by sweating and the appearance of acetylcholine in the eserinizd fluid perfusing the paw.

(8) *Chemical transmission of motor nerve impulses to voluntary muscle.* Evidence that acetylcholine is liberated from the terminals of motor nerves and serves as a transmitter of impulses to the muscle fibers has been obtained by Dale and his associates.

(a) Upon rhythmical stimulation of the hypoglossal nerve of the perfused tongue of the cat, acetylcholine appeared consistently in the venous fluid. Similar results were secured with the perfused leg muscles of the dog during stimulation of the ventral spinal roots after excision of the lumbar sympathetic chain.

(b) The sudden injection of a small dose (2 to 10 γ) of acetylcholine into the artery supplying the gastrocnemius of the cat during circulatory arrest caused a sharp contraction of the muscle. This is a "nicotine action" of acetylcholine; it is annulled by curarine but not by atropine. The direct application of a minute amount ($5 \times 10^{-6} \gamma$) of acetylcholine to the motor end-plate of the muscle fiber causes a short sharp tetanic contraction. Ten times this quantity applied

elsewhere to the fiber is ineffective (Buchthal and Lindhard).

(c) The intravenous administration of eserine (0.2 to 0.3 mgm. per kgm.) to a spinal cat caused an increase of 130 per cent in tension of a gastrocnemius twitch provoked by stimulation of the motor nerve. Eserine had no such effect upon the response of denervated muscle to direct stimulation.

The rôle played by potassium ions in synaptic transmission

The injection of small amounts of potassium chloride into the fluid perfusing the superior cervical ganglion stimulates the nerve cells, and the injection of a sub-stimulant dose augments the effect of a series of submaximal stimuli applied to the preganglionic fibers (Feldberg and Vartiainen). When the concentration of potassium chloride is raised to four times the normal, acetylcholine appears in the venous outflow from the ganglion (Feldberg and Brown). It had been reported previously by Beznak that KCl caused the liberation of acetylcholine in the frog's heart. After section of the cervical sympathetic and degeneration of the preganglionic fibers the addition of KCl to the fluid perfusing the superior cervical ganglion, though still causing excitation of the cells, results in the liberation of an insignificant amount of acetylcholine. This fact indicates that the K ion itself (i.e., quite independent of acetylcholine) has a stimulant action upon the ganglion cells. There has been some discussion of the interpretation of these findings in regard to the rôle played by the K ion in the normal conduction in sympathetic ganglia. Brown and Feldberg found, for example, that curarine, which blocks transmission at synaptic junctions, does so by preventing acetylcholine from acting on the ganglion cell; but it actually enhances the response to KCl. The output of acetylcholine from the preganglionic endings was not affected by the poison. These observations suggest that potassium is not directly concerned in the transmission of the effect across the synapse. Brown and Feldberg suggest that the liberation of acetylcholine under normal circumstances is dependent upon the movement of K ions ("a wave of mobilization of K ions") accompanying the preganglionic impulse and that the appearance of K ions at the synapse also conditions the action of acetylcholine upon the ganglion cell.

That calcium also plays an important rôle in the excitation mechanism has been shown by Bronk and his colleagues who found that the absence of calcium ions caused a long continued spontaneous discharge from sympathetic ganglion cells. Bronk has also reported that doubling the calcium concentration greatly reduces the frequency of the impulses discharged by nerve cells stimulated by acetylcholine. Lowering the concentration of potassium had a similar effect. Either lowering the concentration of calcium or increasing that of potassium increased the frequency of the impulses. Harvey and McIntosh found that

absence of calcium from the fluid perfusing a ganglion results in failure of synaptic transmission and of acetylcholine liberation from the preganglionic terminals. The absence of calcium was not followed by spontaneous activity of the ganglion cells unless potassium was present. It did not result, therefore, when the ganglion was perfused with a 0.9 per cent sodium chloride solution. These observers conclude from their experiments that calcium is necessary in order that potassium can act to liberate acetylcholine from the nerve endings. Impairment of transmission at the myoneural junction has been observed by Brown and Harvey in young animals kept on a diet deficient in calcium.

FIG. 391. Diagram showing the distribution of cholinergic and adrenergic fibers. A, parasympathetic; B, sympathetic; 1, preganglionic; 2, postganglionic, heavy lines, cholinergic; light lines, adrenergic.

From the results of the investigations cited in the foregoing paragraphs a summary can now be given in respect to the liberation of humoral agents from autonomic nerve endings (fig. 391). Acetylcholine is liberated at the endings of parasympathetic fibers such as those of the chorda tympani going to the salivary glands, and of those innervating the sphincter pupillae, heart, stomach, intestine, bronchioles, bladder, erectile tissue, etc. It is also probably set free at the terminations of both parasympathetic and sympathetic vasodilator nerves and of parasympathetic nerves to the intestine and bladder. It is apparently the transmitter of effects between the sympathetic *preganglionic* fiber and the ganglion cell. The nerve impulse reaching the preganglionic terminal liberates acetylcholine which then stimulates the ganglion cell ("nicotine" action). The effect of

acetylcholine upon the ganglion cell appears to be potentiated by potassium ions. The impulse set up in the nerve cell passes along the *postganglionic* fiber and causes the liberation of an adrenaline-like substance from its terminal. Since it is known that each nerve impulse transmitted along a preganglionic fiber causes only one impulse to be discharged along the postganglionic fiber, it is assumed that a fresh quantity of acetylcholine is liberated by each preganglionic impulse and then destroyed by the action of the cholinesterase. It is probable, though so far unproved, that acetylcholine serves as a chemical transmitter between parasympathetic preganglionic fibers and the parasympathetic ganglion cell.

Since anatomical terms fail to express these physiological conceptions Dale suggests that the fibers which liberate acetylcholine be called *cholinergic*, and the term *adrenergic* be used for those which liberate an adrenaline-like substance (sympathin). Thus (a) parasympathetic postganglionic fibers, (b) postganglionic sympathetic fibers supplying the sweat glands and uterus, and (c) sympathetic preganglionic fibers are cholinergic—the “muscarine” action being prominent in the first two instances, the “nicotine” action in the last. (d) The parasympathetic preganglionic fibers and the postganglionic sympathetic fibers causing vasodilatation (see p. 234) are also cholinergic. Postganglionic sympathetic fibers, e.g., to the heart, intestine, etc., as well as those causing vasoconstriction, are adrenergic.

The relation of acetylcholine to synaptic and neuromuscular transmission

The chemical theory in all its aspects has not received universal acceptance. The evidence is virtually conclusive that in the slower types of transmission (muscarine-like action, e.g., at vagal and other postganglionic terminals) acetylcholine plays an essential rôle in the nervous effects. With regard to the more rapid types of transmission (nicotine-like action, e.g., at synapses between preganglionic fibers and ganglion cells, synapses in the central nervous system and their equivalent in striated muscle (namely, the myoneural junction) opinion has been sharply divided. Dale and his colleagues have maintained that in these instances, also, acetylcholine served as the transmitting agent. Eccles criticized this view, mainly on the ground that whereas the action of the cardiac vagus is prolonged, the acetylcholine persisting for seconds, in the synapse a chemical transmitter if it exists must be removed from its site of action within a few milliseconds, i.e., within the refractory period of the postganglionic neuron. He and others have doubted that sufficient quantities of cholinesterase were

produced in the required time. Scepticism was also expressed that acetylcholine, in quantities great enough to stimulate the ganglion cell, could be formed so rapidly. These objections have been met to a large extent by the work of Marnay and Nachmansohn who have furnished evidence of a high concentration of cholinesterase at the motor end-plates. According to their estimation, the concentration of enzyme at these sites is many thousand times greater than in the rest of the muscle.

The rate of production of the enzyme at the muscle end-plates is the basis for the estimation of the formation of its substrate, acetylcholine. In other words, the rate at which acetylcholine is removed is taken as a measure of its production. In this way it has been estimated that about 2×10^{-6} micrograms of acetylcholine can be split at a single nerve ending of the frog's sartorius muscle during the refractory period. This amount which corresponds to the production of 8×10^9 molecules of acetylcholine, is considered to be more than sufficient to stimulate. It has also been found that in a sympathetic ganglion from 3 to 6×10^{10} molecules of the ester can be hydrolyzed within a millisecond.

Those who supported the classical theory of neuromuscular and synaptic transmission, namely, that the action currents set up in the motor nerve or preganglionic fiber excite the muscle or the ganglion cell, point out that the interval between the arrival of the nerve impulse at the motor end-plate and the beginning of the propagated disturbance in the muscle (end-plate delay) is of about the same duration as the “spike” potential. Erlanger has shown also that the nerve impulse can excite the section of nerve beyond a blocked region of from 1 to 2 millimeters in length. He argued, therefore, that it was unreasonable to maintain that discontinuity at a synapse (or presumably at the myoneural junction) would prevent transmission of the impulse. Such facts advanced by the proponents of the electrical theory could not be disregarded, yet, it was difficult to believe that the liberation of acetylcholine by nerve impulses, a fact proved beyond dispute, and the relatively high concentration of cholinesterase at the precise site where it could play an essential rôle in the chemical mechanism are merely incidental and without any physiological significance.

Researches within the last few years have brought these two views into harmony. It has been shown that acetylcholine is formed not only at the terminals of the nerve but also along its course during the passage of the impulse. The ester is concentrated in the outer layers of the fiber, not in the axis cylinder.

Acetylcholine is no longer looked upon simply as a transmitter of effects from the nerve terminal across the synapse. The electrical change and the production of acetylcholine are now considered as two inseparable parts of one process. This applies to transmission at synapses, ganglionic or central, neuromuscular junctions, autonomic terminals and to the conduction of

the impulse in the nerve fiber. The liberation of acetylcholine at central synapses has been demonstrated by Chang. Several observations showing the importance of acetylcholine in neural and neuromuscular processes could be cited. For example, a high concentration of the ester has been found to take place at an early stage of embryonic development, at a time when the muscle end-plates make their appearance, when the first muscular movements occur and when the nervous centers become active. Also, in the brain and cord, the gray matter, which is composed mainly of cell bodies and synapses, as well as the retina and the basal ganglia, the concentration of cholinesterase is many times greater than in the white matter. The synthesis of acetylcholine by brain slices incubated *in vitro* has been demonstrated by Quastel and his colleagues.

The close relationship between acetylcholine metabolism and the E.M.F. of the action potential has been shown clearly by Nachmansohn and his associates in a study of the electric organs of such fish as the electric eel and torpedo. These organs can discharge an electric shock which in some of the larger species amounts to from 400 to 800 volts. The electric organ is composed of plate-like structures arranged in series or columns which are believed to have evolved from the end-plates of skeletal muscle. They resemble in their arrangement a voltaic pile. One side only of each plate is innervated, and this side becomes negative during activity. The other side is positive. High concentrations of cholinesterase are produced in these organs. In some instances several kilograms are formed in an hour, or an amount three or more times the weight of the organ itself. A close correlation has been shown by Nachmansohn and his colleagues to exist in the electric organ of *Electrophorus electricus*, between the number of plates per cm., the E.M.F. per cm. and the concentration of cholinesterase. There remains little doubt that the production of acetylcholine is closely associated with the activation and electrical discharge of these organs. The relationship does not imply that acetylcholine generates E.M.F. directly by an action on the surface at a synapse or myoneural junction. Since $V = E - IR$, the ester might act by reducing the resistance at the surface.

That the action potential is associated with a change in resistance has been shown by Cole and Curtis. Conduction is conceived as occurring in the following manner. Acetylcholine by altering the resistance causes the resting potential to be abolished or reversed. Thus, an electric current is set up which activates the adjacent section of the nerve where the same process is repeated and an impulse is propagated along the fiber (see p. 791).

AFFECTIONS OF AUTONOMIC NERVES

HORNER'S SYNDROME is the name given to the group of effects resulting from section or paralysis of the cervical sympathetic. They are: (a) *Ptosis* (drooping of eyelid) and *enophthalmos* (recession of the eyeball) due to paralysis of the smooth muscle of the upper lid and orbit respectively; reduction in intraocular pressure. (b) *Constriction of the pupil* (myosis). The pupil of the affected side is smaller than its fellow of the opposite side as a result of the unopposed tonic action of the pupillo-constrictor center (see p. 1012). (c) *Vasodilatation, higher temperature and absence of sweating* over the affected side of the face. Irritation of the cervical sympathetic tends to cause the opposite effects, namely, widened palpebral fissure, exophthalmos, dilated pupil (mydriasis) and excessive secretion of sweat on the affected side. In the dog stimulation of the cervical sympathetic causes marked protrusion of the eyeball. The movement is due to the contraction of the circularly disposed smooth muscle fibers in the fascia bulbi. A lesion of the brain-stem or spinal cord may interrupt the central course of the sympathetic fibers to the head, with the production of Horner's syndrome.

The relation of the autonomic system to Raynaud's disease (p. 254), asthma (p. 366), megacolon (p. 508) and spastic states of the skeletal muscles (p. 825) has been considered in other sections.

SECTION IX. THE SPECIAL SENSES

CHAPTER LXXIV

THE PHYSIOLOGY OF VISION. STRUCTURE OF THE EYE. DUPLICITY THEORY. REACTIONS OF THE RETINA; SUBJECTIVE PHENOMENA

ANATOMICAL OUTLINE OF THE EYE

The human eyeball (bulb or globe of the eye) is approximately spherical, being slightly flattened from above down. In the adult it measures to about 24 mm. in its anteroposterior and transverse diameters and 23.5 mm. in its vertical diameter. It is compounded of the segments of two spheres, its posterior $\frac{1}{2}$ being the large segment of a sphere with a radius of about 8 mm. The center of the anterior curvature of the eyeball is called its *anterior pole* and the corresponding point on the posterior surface the *posterior pole*. A straight line joining the two poles is known as the *optic axis*. The visual axis passes through the cornea a little to the nasal side of its center of curvature and the fovea centralis; the optic and visual axes therefore cross at a point a little behind the center of the lens.¹ The circumference of the eyeball midway between the two poles is termed the *equator*. Any imaginary circle drawn to pass through both poles of the eye is called a *meridian*. The *optic nerve* (p. 1008) enters the eyeball a little to the inner side of the posterior pole. The optic axes are nearly parallel, converging only slightly behind, whereas the axes of the optic nerves followed backwards converge sharply towards the center of the *dorsum sellae* of the sphenoid bone (see fig. 392).

A thin fibrous membrane—the *fascia bulbi* or *capsule of Tenon*—encloses the globe from the entrance of the optic nerve to just behind the circumference of the cornea where it blends with the outer coat (sclerotic) of the eyeball. The *fascia bulbi* is pierced a little in front of the equator of the globe by the ocular muscles; it blends with the sheaths of these muscles. Fascial slips (*check ligaments*) pass from the muscle sheaths, especially those of the external and internal recti, to the walls of the orbit and serve, it is believed, to check the movements of the muscles. In the region surrounding the optic nerve entrance the *fascia bulbi* is pierced by the ciliary vessels and nerves and just behind the equator by the vortex veins. The space between the *fascia bulbi* and the globe is occupied by a meshwork of fine areolar tissue, the eyeball thus lies in a cushioned socket, separated from the other contents of the orbit.

THE CONJUNCTIVAL AND LACRYMAL APPARATUS. The exposed part of the eyeball is covered by delicate mucous membrane—the *conjunctiva*—which is reflected

on to the inner surfaces of the eyelids. The ocular surfaces are lubricated and kept clean of fluid secreted by the *lacrymal gland* (fig. 3). The *lacrymal gland* is about the size and shape of an almond. It lies under the shelter of the bone of the upper and outer part of the orbit (i.e., the *lacrimal process* of the frontal bone). It is of the *serous* type, somewhat resembling in structure a *salivary gland*; its secretion—the tears—is carried through a number of fine ducts into the *conjunctival fornix*. The secretion is a clear watery fluid having, according to Ridley, the following composition.

Water	98
Total solids	1
Ash	1
Total N	0
Non-protein N	0
Urea	0
Protein (albumin and globulin)	0
Sugar	0
Chlorides (as NaCl)	0
Sodium as Na ₂ O	0
Potassium as K ₂ O	0
Ammonia	0

A sample of tears collected from the *conjunctival* surface also contains traces of mucus secreted by the *conjunctiva* itself.

Several small accessory *lacrymal glands* are present in the *conjunctival fornices*; their secretion serves for lubrication and cleansing under ordinary circumstances. The main glands are called into play only upon special occasions, e.g., crying, or in response to irritation of the *conjunctiva*.

The winking movements of the lids spread the tears over the *conjunctival surfaces*; the fluid is directed into the *lacrymal lake*—a small triangular area lying in the angle bounded by the innermost portions of the eyelids. The center of the *lacrymal lake* is occupied by a pink structure, composed of modified skin, containing sebaceous glands and a few slender hairs. The tears are drained from the *lacrymal lake* by two small ducts—the *lacrymal ducts*. The minute orifices of these ducts—the *puncta lacrymalis*—may be seen one on the inner margin of each lid. The *lacrymal ducts* lead into the *nasolacrymal duct*; this opens into the

¹ The angle formed by the intersection of the optic axis with the visual axis is about 5° and is referred to as the *angle alpha*.

of the nose; its upper blind end is termed the *lacrimal sac*.

Secretory fibers to the lacrimal gland are derived from the parasympathetic. They arise from the superior salivary nucleus, or, according to some, from a group of cells (*lacrimal nucleus*) in close relation to the former. The fibers leave the brain in the

nerve—a branch of the ophthalmic. The lacrimal nerve thus receives the parasympathetic fibers and delivers them to the lacrimal gland; it also carries sensory fibers to the gland.

Lacrymation is induced reflexly by stimulation of the nerve endings of the cornea or conjunctiva (ophthalmic division of the 5th nerve). The reflex is annulled by anesthetization of the surface of the eye, by section of the sensory nerves or of the great superficial petrosal nerve, or by blockage of the sphenopalatine ganglion. Emotional lacrymation is not affected by local anesthetization nor by section of the ophthalmic division of the 5th nerve, but is abolished by section of the great superficial petrosal nerve or by blockage of the sphenopalatine ganglion. The sympathetic does not furnish secretory fibers to the lacrimal gland. Excessive lacrymation may follow a lesion of the facial fibers central to the facial ganglion. Defective or complete absence of a lacrymatory response, either psychic or reflex is seen, though very rarely, as a congenital anomaly.

THE TUNICS OF THE EYEBALL

The wall of the eye is composed of three concentric layers or tunics. (1) An outer or fibrous tunic—the *sclera and cornea*, (2) a middle vascular tunic—the *choroid, ciliary body and iris*, and (3) a nervous tunic—the *retina* (see fig. 392).

THE OUTER OR FIBROUS TUNIC. [The posterior $\frac{1}{2}$ of this coat is hard, tough and opaque and is called the *sclera*; it is composed of white fibrous tissue and fine elastic fibers. Its anterior $\frac{1}{2}$ is perfectly transparent and is called the *cornea*. The sclera appears in front as the so-called "white of the eye." The point where it joins the cornea—the *sclerocorneal junction*—is marked by a faint groove (see p. 1003). Where it is pierced by the optic nerve is reduced to a thin membrane containing perforations for the transmission of the retinal vessels and the bundles of nerve fibers. This part of the outer tunic, known as the *lamina cribrosa*, is the weakest part of the wall of the globe and is the first to yield to a persistently high intra-ocular pressure (see Glaucoma, p. 1004), producing the so-called "cupping" of the optic disc. The cornea is convex anteriorly, being the small segment of a sphere having a radius of about 7.7 mm.² It is almost circular in circumference, measuring 11 mm. and 12 mm. respectively in its vertical and horizontal meridians. It is from 0.5 mm. to 1 mm. in thickness. The cornea is composed of five layers in the following order from before backwards; (a) the corneal epithelium, (b) the anterior elastic lamina of Bowman, (c) the substantia propria, (d) the posterior elastic lamina of Descemet, and (e) a layer of endothelial cells (fig. 394).

The corneal epithelium is continuous with that of the

² The peripheral zone is somewhat flattened as compared with the central portion; the former has a radius of about 6.8 mm.

intermedius of Wrisberg, the sensory root of the 5th nerve. They pass to the geniculate ganglion which they join in the great petrosal nerve (see fig. 365, p. 861). The sensory root of the 5th nerve joins the deep petrosal nerve to form the sphenopalatine ganglion. The fibers of the sphenopalatine ganglion join the pterygoid canal (Vidian nerve). The fibers are conveyed in the latter nerve to the sphenopalatine ganglion and thence into the zygomatic branch of the 5th nerve. A branch of the zygomatic nerve (zygomaticotemporal) anastomoses with the lacrimal

conjunctiva; it consists of several strata of cells of different sizes and shapes. Columnar cells compose the deepest layer; this is overlaid by two or three layers of polyhedral cells. The cells of the superficial three or four layers are of the squamous type. The *substantia propria* is a tough transparent membrane consisting of a number of flattened lamellae composed of bundles of modified connective tissue fibers continuous with those of the sclera. The *anterior elastic lamina of Bowman* and the *posterior elastic lamina of Descemet* bound

through the anterior elastic lamina where they form a subepithelial plexus; nerve filaments can be traced from the latter to the epithelial cells. The pain fibers have a very low threshold being aroused by very minor forms of stimulation. This has led to the general belief that the cornea is devoid of touch receptors and that stimuli which give a sensation of touch when applied to the skin are painful if applied to the cornea. It is claimed, however, that certain weak and innocuous

FIG. 394. Section of human cornea; 1, epithelium; 2, anterior elastic lamina; 3, substantia propria; 4, posterior elastic lamina; 5, endothelium of the anterior chamber. (After Waldeyer, modified.)

FIG. 395. Layers of retina. (After Cajal.)

the corresponding aspects of the substantia propria. At the circumference of the cornea the posterior elastic lamina breaks up into fibers which are continued into the pectinate ligament (p. 1003). The cornea is devoid of blood vessels; it receives nourishment from lymph derived from vessels at its margin, and which percolates through the spaces between its cells. It is supplied around its circumference by a rich plexus of pain fibers. Fine non-medullated filaments derived from this plexus pass through the posterior elastic lamina and form a second plexus in the substantia propria (stroma plexus). From the stroma plexus fibers proceed outwards

stimulating agents, such as a jet of fluid impinging upon the cornea, arouse a sensation of touch alone.

The MIDDLE OR VASCULAR LAYER consists from behind forwards of the *choroid*, *ciliary body* and the *iris*. The choroid is composed of a rich capillary plexus and the numerous small arteries and veins leading to and from it. It is dark brown in color, due to the presence of pigment cells, and forms the middle layer of the posterior $\frac{2}{3}$ of the globe; it terminates anteriorly at the level of the ora serrata of the retina. The ciliary body is described on p. 993 and the iris on p. 1012.

THE NERVOUS TUNIC OR RETINA. The retina is

composed of seven layers of *nervous elements*, an outermost layer of *pigment cells* and two *supporting membranes*. The following is a list of the ten retinal layers from within outwards (see also fig. 395).

1. *Internal limiting membrane*
2. Layer of optic nerve fibers (stratum opticum)
3. Layer of ganglion cells
4. Inner plexiform or reticular layer
5. Inner nuclear layer
6. Outer plexiform or reticular layer
7. Outer nuclear layer
8. *External limiting membrane*
9. Layer of rods and cones
10. Pigment layer (stratum pigmenti)

The *layer of optic nerve fibers* is composed mainly of the naked axons of the ganglion cells composing the subjacent layer. They make a sharp turn a short distance from their origins and converging towards the posterior part of the globe form the optic nerve.

The *layer of ganglion cells*. There are several (five at least) varieties of these cells. Some are large (giant ganglion cells), others quite small (midget ganglion cells). They also differ in shape; oval, pyriform and multipolar forms can be distinguished. The axons of the ganglion cells compose the first layer mentioned above; their dendrites pass outwards to ramify in the outer plexiform layer where they form synaptic connections with the bipolar cells (see below). Each ganglion cell is synaptically connected to a number of bipolar cells, and through such relations with a large number of visual receptors. One type of ganglion cell of small size, namely, the midget ganglion cell, though it is connected with several diffuse bipolar cells, forms connections with only one midget bipolar.

The *inner plexiform layer* is made up mainly of the dendrites belonging to the ganglion cells and to the cells of the inner nuclear layer. There are, in addition, a few small horizontal nerve cells possessing short branching processes.

The *inner nuclear layer* is constituted of three types of cell. (a) *Bipolar cells*. These possess oval bodies and two long slender processes which arise from opposite poles. There are two main varieties. (i) The *diffuse bipolars* are the most numerous. Their outwardly directed processes (dendrites) synapse with both rods and cones. The other process connects with a ganglion cell. Their dendritic processes show considerable overlapping. (ii) "Midget" bipolars are much smaller and less numerous. Their dendrites do not overlap. In the foveal region each cell synapses with a cone cell but in the extrafoveal retina several cones are synaptically connected with a single midget bipolar. (b) *Horizontal cells*. These are small flattened stellate or larger irregularly shaped elements whose axons run horizontally. They are purely associative in function, their short dendritic processes forming contact with a cone fiber, and their axons to a more distant group of rods and cones. (c) "*Amacrine*" cells. Many of these appear to possess no axons. Their dendritic processes

for the most part ramify in the inner plexiform layer (*diffuse* type). The dendrites of others do not leave the inner nuclear layer (*stratified* type). The axons of some can be seen ramifying in the outer plexiform layer. The polarity of the amacrine cells appears to be in the centrifugal direction, and, therefore, opposite to that of the bipolar and ganglion cells, which convey impulses centripetally.

The *outer plexiform layer* is made up of the ramifications of the process of the bipolar and horizontal cells of the inner nuclear layer and the terminations of the rod fibers and cone fibers.

The *outer nuclear layer* is composed of the cone granules and fibers and the rod granules and fibers.

The nervous elements of the various layers are supported by a framework of fibers of neuroglial character (sustentacular fibers of Mueller). They extend from the inner aspect of the stratum opticum where they constitute the *internal limiting membrane* to the bases of the rods and cones where they break up into a fine feltwork of fibers to form the *external limiting membrane*.

The *layer of rods and cones*. The *rod and cone cells* (fig. 396) are the visual receptors. Both these elements lie with their long axes perpendicular to the retinal surface. The rod cell (40μ to 60μ long) consists of two well-defined portions, a cylindrical outer segment—the *rod*—which extends from the external limiting membrane to the pigment layer, and an inner segment—the *rod fiber*. The latter is a long slender filament swollen at a variable distance along its course by the cell nucleus—the so-called *rod granule*. The inner end of the rod fiber shows a slight enlargement called the *end button* or *spherule* which makes connection with the arborizations of the bipolar and horizontal cells in the outer plexiform layer. The rod itself shows two segments of about equal length, but the outer one is only about half the thickness of the inner and is marked by transverse striae. The two parts of the rod differ chemically, each reacting in its own way to certain dyes; the outer thinner portion is composed of a myelin-like material, the inner, of protoplasm. The outer segment breaks up after death along the striae just mentioned into tiny transverse plates; this part of the rod alone contains a reddish pigment—the *visual purple* or *rhodopsin* (p. 970).

The cone cell consists of a pyramidal portion—the *cone*—situated on the outer side of the external limiting membrane with its pointed end directed towards the pigment layer, and an inner segment—the *cone fiber*—which varies in length and thickness according to the part of the retina in which it is situated. The cone fibers contain the nuclei; these are the *cone granules* already mentioned with the rod granules as being the chief elements of the outer nuclear layer. The cone cells vary from 28 to 85 microns in length in different parts of the retina, and from 2.5 to 7.5 microns in thickness.

The number of receptors in the human retina according to most recent estimates is about 115,000,000 rods

and 6,500,000 cones. In the fovea each cone is believed to have its own nerve fiber, whereas in the peripheral retina a single fiber is distributed to about 80 receptors. It is evident that light in order to reach the rod and cone layer must pass through all the other nervous layers. The retina has been compared to a transparent carpet laid upside down (Walls). The pile then corresponds to the visual receptors and the jute backing to the maze of nerve fibers which support the visual and integrate the impulses initiated in them.

The *pigment layer* consists of a single row of epithelial cells containing mobile rod-shaped granules of a dark brown melanin-like pigment called *fuchsin*. The outer surfaces of the pigment cells are hexagonal in outline (fig. 396) and are firmly attached to the choroid. From

expands, while the proximal portion remains narrow and is termed the *optic stalk*. As development proceeds the outer wall of the optic vesicle collapses and becomes invaginated; finally, it seems the inner wall and with it, thus a two-layered cup-shaped structure—the *optic cup*—is formed. The deep layer consists of a single row of epithelial cells which acquire pigment, is seen in the adult retina as the *stratum pigmentum*. The invaginated wall becomes thickened, and from it are developed the nervous layers of the retina. At birth the nervous layers (retina proper) can be readily stripped up from the pigment cells which remain attached to the choroid. The membrane freshly detached from the pigment layer appears reddish (due to presence of visual purple) and, transparent when shielded from strong light. Upon exposure to bright light, however, it rapidly becomes colorless (bleached) and clouded. The line of union between the two walls of the optic cup is always a weak part in the adult retina and in the living eye detachment of the retina from the pigment layer is not an uncommon accident.

The retina proper extends from the margins of the optic papilla (see below) to just behind the ciliary body. At this point it ends abruptly in a dentated border—the *ora serrata* (see fig. 447, p. 993). Its thickness diminishes progressively from the optic papilla (where it measures about 0.4 mm.) to the dentate border where it is only 0.09 mm. thick. The pigment layer is continued forwards from the *ora serrata* over the deep surface of ciliary body (*pars ciliaris retinae*) and iris (*pars iridica retinae*). Two retinal areas require special mention—the *optic disc* and the *macula lutea* with the *fovea centralis*.

The *optic disc* is situated about 3 mm. to the nasal side of and a little above the posterior pole of the eyeball; it has a diameter of about 1.5 mm. in man. When viewed in the human eye subject by means of the ophthalmoscope (p. 988) it appears as a pink circular area fading to a creamy white toward the center. It is pierced near its center by the retinal vessels—the *arteria centralis retinae* and its accompanying vein (Pl. 2, opposite p. 989). The circumference of the optic disc is elevated to form the *optic papilla*. The central depressed part is known as the *physiological cup* or the *excavation of the optic nerve*. The vessels climb up the inside of the cup to reach the retina. All layers of the retina except the nerve fiber layer are absent from the optic disc. It is therefore totally insensitive to light and is known as the *blind spot* of the retina. The reader is referred to fig. 463 for a demonstration of the blind spot in his own eye.

The macula lutea. A small diffuse yellow area called the *macula lutea* (yellow spot) is seen in the retina a little to the temporal side of the posterior pole of the globe, i.e., about 3.5 mm. from the outer edge of the optic disc. Its color is due to the presence of a yellow pigment which, like the visual purple, is bleached by light though much less readily. The central zone of the macula lutea is depressed and is referred to as the *fovea*

FIG. 396. A, rod; B, cone; C, pigment cells viewed from the surface.

their inner portions fine processes arise which are insinuated between the rods and cones. In darkness or dim light the pigment granules are aggregated in the inner half or so of the cell body but in certain species, e.g., the frog and fishes—not in mammals—(p. 973), illumination of the eye causes them to move into the processes between the visual cells. The pigment serves, like the black paint on the inside of a camera, to absorb light which otherwise would be diffused and cause blurring of the retinal image. In albinos the hexagonal cells are free from pigment.

DEVELOPMENT OF THE RETINA AND DESCRIPTION OF ITS GROSS APPEARANCE. Knowledge of the origin of the retina is an important step towards an understanding of its functions. It is developed from a hollow outgrowth of the rudimentary fore-brain called the *optic vesicle*. The distal portion of this diverticulum

macula lutea. This is the region of the retina concerned with acute vision; in man it has a diameter of about 0.44 mm. (Wolfrum). The depression is due to the extreme thinning of the retina proper at this point, brought about by the disappearance of the nerve fiber, ganglion cell, inner plexiform, inner nuclear and outer plexiform layers. The elements which compose these layers are absent peripherally, leaving only the cone cells which are here exceptionally long (85μ) and slender (fig. 397). At the bottom of the fovea the thickness of the retina is only 0.1 mm. Moreover, the cone fibers of this region are elongated and, instead of passing perpendicularly inwards, incline obliquely to connect with the bipolar cells around the margins of the fovea. In this region a layer is formed which, though it corresponds to the outer nuclear layer, differs in appearance from that of any other part of the retina. It is called the *outer fiber layer of Henle*. In this region it alone overlies the pigment layer. The pigment layer is exceptionally well-developed at the fovea.

THE OCULAR CIRCULATION. Thirty-three separate arteries enter the globe. The *retina* is supplied by the *arteria centralis retinae*, a branch of the ophthalmic artery. The central artery with its companion vein pierces the optic nerve about 1.25 cm. behind the eyeball and bending sharply runs forwards in the center of the nerve. Perforating the lamina cribrosa it appears inside the eyeball at the center of the optic disc. It immediately divides into two main branches which redivide to form a vascular network, the finer channels ending in a capillary plexus which extends outwards as far as the inner nuclear layer. The fovea itself is devoid of vessels. The vessels of the *choroid* are derived from the long and short posterior ciliary arteries, branches of the ophthalmic, and from the anterior ciliary arteries which are twigs of the lacrymal branch of the ophthalmic. The two long posterior ciliary arteries pierce the sclera a short distance from the optic nerve and, running forwards on either side of the globe between the choroid and the sclera, anastomose with

FIG. 397. Section through the centre of the fovea centralis. (From Wolff, after Eisler.)

As a result of the displacement of the retinal elements from the fovea, and of the greater size of the ganglion cells, the macular retina is unusually thick around the foveal margins.

The fovea is rod-free. In the remainder of the retina the cones diminish progressively in number from the foveal margin to the periphery, while the rods increase proportionately. The macula immediately surrounding the fovea is nearly but not quite rod-free. In some animals, e.g., the rat and certain night-flying birds, the retina throughout contains only rods; in others, especially day birds, rods are almost entirely absent.

It must never be forgotten that the retina is an outgrowth of the brain and retains the structural and functional characteristics of nervous tissue. The neurons composing its several layers are connected through synaptic junctions, and such phenomena as temporal and spatial summation, latency, inhibition, convergence and occlusion (see Chapter LXV) have been demonstrated in the retina. As already mentioned, a single ganglion cell of the retina can receive over convergent pathways impulses from a number of visual receptors.

branches of the short posterior ciliary arteries and of the anterior ciliary artery to form a vascular ring (*circulus arteriosus major*) which encircles the periphery of the iris. Branches pass from this vascular circle along converging lines through the tissue of the iris to the pupillary margin; here they join to form a smaller arterial ring (*circulus arteriosus minor*). The short posterior ciliary arteries perforate the sclera around the optic nerve and supply the choroid and ciliary processes. The anterior ciliary arteries and their companion veins pierce the globe a little behind the sclerocorneal junction. The blood is returned from the choroid by a system of veins in the outer choroidal layer. From their whorl-like arrangement they are termed the *vortex veins* (*venae vorticales*). The smaller and medium sized vessels of this system become confluent to form four trunks which penetrate the sclera and appear on the surface of the globe equidistant from one another just behind its equator. These vessels and the anterior ciliary veins drain into the ophthalmic veins. The central vein of the retina empties into the cavernous sinus either directly or through one of the ophthalmic veins (p. 990).

In man the pressure in the central artery of the retina is from 70 to 85 mm. Hg systolic and from 40 to 50 mm. diastolic. But owing to the presence of the intra-ocular fluid and the resistant nature of the sclerotic coat, pulsation of the retinal artery as observed by ophthalmoscopic examination is slight. The pressure in the retinal artery of the intact globe may be determined by the method of Bailliart which consists in observing the vessel with the ophthalmoscope while a measured pressure is made upon the globe. Maximal pulsation is taken as indicating the diastolic level and the disappearance of pulsation as an index of the systolic pressure. There are several fallacies in this or any other indirect method, the results being far from reliable. The pressure in the central vein of the retina is around 25 mm. Hg. A venous pulse is also observed; it is attributed to the transmission of the impulse from the artery through the intra-ocular fluid to the veins. That is to say, with each expansion of the artery the veins for a short distance proximal to where they leave the orbit are compressed and an extra quantity of blood is ejected from the eyeball.

The lens and ciliary body are described on pp. 993 and 994, the visual pathway and ocular muscles in Chapter LXXII.

THE DUPLICITY THEORY OF RETINAL FUNCTION

The theory that the retina is a duplex organ was first proposed by Schultz in 1866. There is today abundant evidence for Schultz's conception that the rods function in dim light, registering colorless-sensations only (*scotopic vision*), whereas the cones are active in bright light and are sensitive to color as well as to white light (*photopic vision*). The fovea, being composed entirely of cones, is the region where photopic vision reaches its highest state of efficiency. The surrounding (peripheral or extra-foveal) retina is composed of both rods and cones, the proportion of the former type of element increasing, that of the latter diminishing towards the periphery where cones are entirely absent.

At the risk of some repetition in other sections the evidence for the duplex nature of retinal function will be briefly reviewed.

(1) *The Purkinje shift.* When the spectrum is viewed in a bright light (i.e., by the light adapted eye, p. 968) it is seen as a series of colors with the maximum brightness (luminosity) in the yellow (sodium D-line). If the illumination of the spectrum is reduced and the eye dark adapted, the region of maximum luminosity will be found to have shifted nearer the violet end. The red portions gradually become darker, the blues correspondingly brighter, and with further reduction in the intensity of the light a point is reached where the spectrum is colorless; the maximum luminosity is now in the region of the E line (see plate 1 and fig. 398). A

Purkinje effect cannot be demonstrated at the fovea (cones only). It is evident from fig. 399 that there is no correspondence between the curve representing distribution of radiant energy in the spectrum and luminosity curves.

(2) *Evidence from the visibility curves.* In twilight vision the fovea is almost blind; vision is then mainly a function of the outlying retina which manifests enormously increased sensitivity. When the different regions of the retina are compared, it is found that the most effective wave length in causing a just perceptible sensation is 554 μ for the fovea and 510 μ for the outlying part of the retina (in testing the fovea the eye is light adapted, but is dark adapted when the peripheral retina is being examined (p. 968)). When

FIG. 398. Normal scotopic (A) and photopic (B) luminosity curves. (After Abney and Festing.)

FIG. 399. Curves showing the relative energy and luminosity of the different regions of the spectrum (Starling, Principles of Human Physiology, 3rd Edition, Lea & Febiger.)

relative energy required to produce a certain sensation is plotted against the wave length the curves shown in fig. 400 are obtained. A visibility curve differs from a luminosity curve in that for its construction the actual energy values at the different wave lengths are taken into account, the energy of the light stimulus being kept constant while the wave length is varied (*equal energy spectrum*); such a curve therefore represents the variations in the sensitivity of the retina purely as a function of the wave length. Separate physical measurements (e.g., by means of a radiometer) must, of course, be made in order to determine the energy values.

(3) Using the electroretinogram (p. 973) as the criterion of retinal response Graham and Riggs found that a Purkinje effect could not be demonstrated in the white rat. The wave length of maximum effective

was the same in both the light and dark adapted eye, namely, 510 $m\mu$, which, as just stated, is that for dark adapted eye of man. The significant point is that the retina of the white rat contains only rods. In such forms as the frog and fish which possess both rods and cones the Purkinje shift can be demonstrated. On the other hand, the retinas of day birds such as the domestic hen and the pigeon, which contains cones but very few rods, show a spectral sensitivity corresponding to that of the light adapted human eye, whereas night birds such as the owl, and other mammals as well as the rat, e.g., the cat, dog and rabbit, whose retinas contain only rods, show a spectral sensitivity similar to that of the human retina in dim light.

Potential changes recorded from the human eye by the illumination of the retina with red and blue light give further evidence for photopic and scotopic mechanisms (Adrian). With red light, which

furnish additional evidence of the dual nature of retinal function.

(7) *The perception of movement* is more acute in the peripheral retina than at the fovea.

THE REACTIONS OF THE RETINA; SUBJECTIVE PHENOMENA

MECHANICAL AND ELECTRICAL STIMULATION. The visual cells—the rods and cones—are highly specialized for the reception of radiations of the visible spectrum and for the conversion of the radiant energy into nerve impulses. The retina, in the expressive phrase of Sherrington, is a “glorified heat spot.” But, though it is stimulated most effectively by light, which is therefore the *adequate stimulus*, crude visual sensations can be evoked by mechanical and electrical forms of

FIG. 400. Visibility curves for scotopic and photopic vision. (After Hecht.)

stimulates mainly the cones, the record shows a brief biphasic change which is increased only slightly by dark adaptation. Blue light, which stimulates the rods predominantly, results in a slower monophasic response. This response is increased greatly by dark adaptation.

(4) The sensitivity of the human retina beyond the fovea is enormously increased by dark adaptation, whereas the fovea shows relatively little change. The color sense is completely lacking from the most peripheral part of the retina which is cone-free (p. 955).

(5) *Night blindness.* In this condition, which is usually due to vitamin A deficiency but may be hereditary, vision is defective in dim lights; whereas daylight vision is normal and the spectral sensitivity of the fovea is that of the normal eye. The visual purple of the rods is lacking or regenerates very slowly in the dark after exposure to light. These facts accord with the belief in the independent function of the rods.

(6) *Visual acuity* (p. 961) and the *discrimination of light intensity* (p. 965). Investigations of these faculties and of the phenomenon of *flicker* (p. 966)

stimulation. Pressure upon the eyeball, for example, causes a luminous ring, known as a *phosphene*, to appear; and the flash of light caused by a blow upon the eye is familiar to everyone. A phosphene also results from electrical stimulation of the eyeball.

As in the case of nerve or muscle, chronaxie is a measure of retinal excitability. Verryp and Bourguignon and associates have investigated the chronaxie of the human retina, employing the phosphene response to electrical stimulation. There are apparently two chronaxies, one due to the rods, the other to the cones. With the electrodes nearer the fovea (cones) the value was from 2.1 to 2.8 σ (sigmas or milliseconds), when nearer the periphery of the retina 1.0 to 1.9 σ . The chronaxies are the same whether the eye is light or dark adapted (p. 967).

STIMULATION OF THE RETINA BY LIGHT

The wave lengths (λ) of radiant energy which stimulate the retina (visible spectrum) range from

around 320 $m\mu$ to 750 $m\mu$ (3200 to 7500 Angstrom units³). This is only about one octave of the entire energy spectrum. The last figure just given evidently represents the limit of sensitivity of the retina to the longer wave lengths, for the media of the eye will transmit infra-red rays up to λ 20,000 $m\mu$. On the other hand, the absolute limit of transmissibility of the shorter waves is about 320 $m\mu$; this figure applies only if the illumination is intense and even then few under 400 $m\mu$ reach the retina. The failure of the retina to respond to rays of waves of shorter length than this is apparently because the ocular media are opaque to them.⁴

The cornea transmits rays from λ 297 $m\mu$ to λ 20,000 $m\mu$ though the transmission above λ 17,000 $m\mu$ is small (2 to 20 per cent). Of the rays reaching it, the lens transmits only a small proportion of those below λ 400 $m\mu$ or above λ 13,500 $m\mu$, and none below λ 300 $m\mu$. That is to say most of the rays between λ 400 $m\mu$ and λ 297 $m\mu$ are absorbed by either the cornea or the lens. Wave lengths between 350 $m\mu$ and 400 $m\mu$ cause fluorescence in the lens. The phenomenon of fluorescence, in general, is attributed to the transference of the energy of the incident radiations to particles of the substance absorbing them. The particles then act as independent light sources, emitting waves which are, for the most part, longer than the original radiation. Thus, the lens converts the harmful shorter waves to longer ones which are permitted to reach the retina. That wave lengths shorter than those which are transmitted by the lens are capable of stimulating the retina is shown by the fact that the visible spectrum is extended towards the blue end after removal of a lens of normal transparency. In old age, on the other hand, the lens becomes more opaque; the upper limit of visibility is around λ 400 $m\mu$ and in the early stages of, the cataractous lens (p. 998) the upper limit is raised to λ 440 $m\mu$.

The quantity of light energy⁵ necessary to simulate the retina is not constant for all wave lengths

$$^3 m\mu \text{ or millimicron} = \frac{1}{1,000,000} \text{ mm.}; \text{ an Angstrom unit (A.U.)} = \frac{1}{10,000,000} \text{ mm.}$$

⁴ The X-rays, of course, penetrate the eye and to such the retina is sensitive. This may be demonstrated by means of metal letters or figures placed in front of a normal eye with closed lids or before any eye in which the retina is normal. A word can be read in this way; the letters when exposed to the rays are clearly recognized as shadows (not images) against a bright ground. The rays are not refracted and the shadows are not inverted upon the retina; therefore, if they are to appear upright to the subject they must be placed in the reverse position in front of the eye (see p. 987).

⁵ Radiant energy is expressed in *ergs*. The erg is a purely objective or physical unit, being quite independent of visual sensations. The energy is measured by

of the visible spectrum. In the dark adapted eye the energy required to stimulate the rods and cause a just perceptible sensation is least for green light with a wave length of about 507 $m\mu$ (see p. 967) and has been estimated by Hecht at from 2.2 to 5.7×10^{-10} ergs⁶, measured at the surface of the cornea in the dark adapted eye. This equals from 58 to 148 quanta of light. After allowance was made for loss of energy in transmission to the retina through the ocular media and for incomplete absorption by the rods, the value was only from 5 to 14 quanta or one quantum absorbed per stimulated rod. The extraordinary sensitivity of the retina to light may be expressed in simpler terms by saying that light emitted by a standard candle at a distance of nearly a mile would be visible if the air were perfectly transparent. Such examples indicate that the eye has a sensitivity some 300,000 times greater than that of the

means of a thermopile, bolometer or radiometer. The *meter candle* is a unit which is in part subjective and in part objective. It is a measure of surface illumination, being defined as the light *incident* per second per sq. cm. of a surface placed at right angles to the beams from a standard (international) candle 1 meter distant (a standard candle is made of spermaceti, weighs $\frac{1}{4}$ lb. and burns 120 grains of wax per hour with a flame 45 mm. high). Illumination is measured by means of a photometer. If, for example, the illumination of a lamp is to be measured, a photometer is set up at this point, and a standard candle is moved until its light just matches that of the lamp. If the candle's distance

in meters is d , then the surface illumination is $\frac{1}{d^2}$. The meter candle is thus a measure of the visual stimulus, not of the sensation itself. The quantity of light *reflected* from a perfectly diffusing surface (e.g., of magnesium oxide) illuminated by 10,000 meter candles is termed a *lambert* (l); a millilambert (ml) is $\frac{1}{1000}$ lambert. The *lumen* is the unit of *emitted* light (*luminous flux*). One lumen is the light emitted in a *unit of solid angle* by a uniform point source of 1 standard candle. A point source is regarded as occupying the center of a sphere; a unit solid angle is the angle subtended at the center of the sphere by an area on its surface equal to the square of the radius. The area of a sphere is $4\pi r^2$, therefore 1 standard candle emits 4π lumens. The intensity of a light source is expressed in lumens, i.e., the luminous flux emitted in any direction per unit of solid angle.

The *photon* is the unit of the *sensation of brightness*. The brightness of an object to the eye depends not only upon the light which it reflects, but also upon the quantity of light which enters the eye, i.e., upon the brightness of its retinal image and upon the state of the retina, whether dark or light adapted (p. 967). The brightness of the image varies, of course, with the diameter of the pupil. A photon is therefore defined as the light in millilamberts multiplied by the area of the pupil in sq. mm. For example, if the illumination of an object is 10 ml and the diameter of the pupil 6 mm. (area = $\pi r^2 = 3.14 \times 9 = 28.26$ sq. mm.) then the brightness is ($28.26 \times 10 =$) 282.6 photons.

⁶ The quantum of green light is 3.84×10^{-18} ergs.

most delicate radiometer and about 3000 times greater than that of a rapid photographic film. The minimum quantity of light energy required to evoke a visual sensation increases progressively towards either end of the spectrum, being several thousand times greater for red and blue than for green light.

The quantity of light energy, i.e., the intensity of the light in the physical sense, required to cause a just perceptible sensation—the *intensity threshold*—is therefore a function of the wave length. The sensitivity also varies in different regions of the retina (p. 956) with the state of adaptation of the eye (p. 967) and with the illumination of the surrounding field.

The intensity threshold is influenced by two other factors, (a) the duration of the stimulus and (b) its extensity, i.e., the size of the light source. At the threshold, the product of intensity, duration and extensity is constant within limits. For example, if a light of a given intensity and size and acting for a given length of time is just below the threshold of visibility, it is perceived upon raising the value of any one of these factors. Or if a light of a certain intensity, duration and size is just visible it becomes invisible if one of these factors is reduced. The relationship between intensity and area (*intensity* \times *area* = *constant*) is known as Ricco's law.

Anyone who has used a camera will recognize that in respect to the relationship between intensity and duration the retina behaves like a photographic film—the lower the illumination the longer must be the exposure, and vice versa. As a matter of fact, the retina obeys the Bunsen-Roscoe law applicable to photosensitive reactions in general (*intensity* \times *time* = *constant*). In the case of the retina this relationship holds only for periods of less than about $\frac{1}{2}$ of a second. Also, the relationship between intensity and area is valid only for retinal areas under about 0.8 sq. mm. It would appear from the foregoing considerations that the total quantity of light energy falling upon the retina within a given time is the fundamental factor which determines the retinal response.

The smallest area which can be perceived is called the *minimum visible*. The angle subtended at the nodal point of the eye by the minimum visible is referred to as the *minimum visible angle*. But from what has been said it is quite evident that neither of these can be given any absolute value. A light could be reduced in size indefinitely to a mathematical point—and, provided it were

sufficiently intense, would still be visible; a star, for example, subtends an infinitesimal visual angle.

VISUAL ACUTY, THE RESOLVING POWER OF THE EYE. The acuteness of vision (or visual acuity) is dependent upon several retinal functions, e.g., the sensitivity to light (intensity threshold), the minimum visible and the ability to recognize the separateness of two closely approximated points or parallel lines. The threshold of the latter faculty is commonly referred to as the *minimum separable*¹ or the *resolution threshold*. Visual acuity is the basis of the *form sense*, by which is meant the power of determining by sight the shape, form, outline and minute detail of our surroundings. Visual acuity is customarily expressed in terms of the minimum separable or, to be more explicit, as the reciprocal of the angle subtended at the nodal point of the eye—the *visual angle*—by the space

FIG. 401. See text.

FIG. 402. See text.

between two objects situated at the minimum distance apart at which their duality can be recognized. For example, if the visual angle is 1.321 minute, then the visual acuity is ($\frac{1}{1.321}$ =) 0.756. The average normal eye can resolve two points when the visual angle is 1 minute (60 seconds). The minimum angle that has been reported is 44 seconds (vis. ac. 1.492). As an object is moved away from the eye its visual angle becomes progressively smaller. Consequently, those details of form and structure which subtend an angle of a minute or more at the nearer point and are therefore visible, gradually become imperceptible with increasing distance. In other words, in order to see an object at a distance as clearly as when it is near the eye, it would need to be increased proportionately in size (see fig. 401).

In determining the visual acuity figures such as the broken circle **C** of Landolt or Snellen's prong, **E**, painted black on a white ground and in graded sizes are employed. The subject is seated at a distance of 6 meters (20 feet) and a figure is placed with the gap

¹ The minimum separable is analogous to two point discrimination in cutaneous sensation (p. 800).

of the **C** or the prongs of the **E** turned to the right or left; he is asked to say in which position the figure is directed. The width of the lines composing the figures and the gap in the **C**, or the spaces between the prongs of the **E**, subtend angles of various degrees, depending on the size of the figure, when placed at a distance of 6 meters. The width of the whole figure is five times that of its parts. By finding the smallest figure whose position can be recognized the visual acuity of the subject (in terms of the visual angle) is ascertained. In testing the visual acuity for the fitting of glasses Snellen's *test type* is most commonly employed. This test is devised upon the basis that two points or lines separated by a space having a visual angle of 1 minute can be resolved by the average normal eye. The test type comprises nine rows of block letters printed in black upon a white card. The rows are arranged in descending order of size from above down. The width of the lines forming the letters of the first row subtends an angle of 1 minute at 60 meters from the eye, while that of the letters in the other rows, two to nine, have a visual angle of 1 minute at 36, 24, 18, 12, 9, 6, 5 and 4 meters, respectively. The card is placed in a good light, the patient is seated facing it at a distance of 6 meters and asked to read down as many rows as he can. The visual acuity is expressed as a fraction, the numerator being the distance at which the subject is seated from the card and the denominator the distance at which the letters could be read by the normal eye. Thus, if he reads the seventh row of letters, i.e., those with a visual angle of 1 minute at 6 meters his vision is $\frac{6}{7}$ or normal. If, on the other hand, he can see distinctly only as far as the fourth row, which the normal eye can read at 18 meters, his vision is $\frac{6}{18}$; if as far as the third row his vision is $\frac{6}{24}$, and so on, for any other row which he is just able to read.

Knowing the distance of the nodal point of the eye from the retina and the visual angle, the size of the retinal image of an object can be calculated (p. 988). With a visual angle of 1 minute the space on the retina separating two point images is 4.4μ . The diameter of a foveal cone is given by different observers as between 2.5 and 4.0μ . Even if the higher of these figures is taken, then the image of two dots separated by 4.4μ would fall upon two cones separated by a single unstimulated cone or by one stimulated differently, i.e., by the image of the interspace (fig. 402).

From such calculations it has been argued that cone diameter is the limiting factor in discriminating two points or thin lines, for obviously with an interspace less than a cone width the two dots would fall upon a single cell, and from what is known of the nerve impulse it cannot be admitted that two parts of a visual receptor upon receiving simultaneously different types of stimulus can give rise to dissimilar sensations.

Difficulties stand in the way of so simple an explanation. The eyes, even with the most exact fixation,

are constantly executing fine movements, a fact which precludes the possibility that the retinal image stimulates any set pattern of cones; the image must be constantly shifting its position. This theory must make the assumption that when the angular distance separating two objects is about the diameter of a cone the two images must be dodged about with almost incredible precision, so that they come to lie not adjacent cones (see fig. 402) but on two cones separated by an unstimulated cone or by one stimulated differently. Adler concluded from his experiments, in which fixation as exact as possible was secured, that a point image moves over from 2 to 4 cones at least. Furthermore, the size of the image on the retina cannot, owing to the diffusion of light, be calculated with the precision implied by the foregoing calculations (see below). It is true that the smallest visual angle recorded ($44''$) for a space between two visually discrete objects would give a retinal image larger (3.2μ in diameter) than some of the estimations (3.0μ) of cone diameter—a fact which fits the theory that the latter is the limiting factor. Nevertheless, it is probable that the correlation is more than a coincidence.

FIG. 403. Description in text.

Wilcox and Purdy suggest that the essential factor is the total illumination of the central cone as compared with its fellow on either side. Thus, in fig. 403 A, cone 2 receives more light than cones 1 and 3. There is a reason then theoretically why the interspace separating two lines could not be narrower than the width of a single cone and still be recognizable. A limit would be reached, however, when the white interspace was reduced to about half the width of a cone; then all three cones must be illuminated equally. It may be asked, what essential difference is there between the minimum visible (p. 961) and the minimum separable? That the minimum visual angle should be so much greater in the one instance than in the other? Two parallel black lines upon a white surface are recognized as separate because a third white line is seen between them. Why then, provided it is bright enough can it not be seen, even though reduced to an almost infinitesimal width? The difference in the two instances appear to be a matter of the background and may be illustrated by fig. 403 B. A bright light upon an extensive background illuminates a single row of cones while all cones for a distance on either side are unilluminated. According therefore to the conception of Wilcox and Purdy, no difference exists, in so far as the fundamental retinal process is concerned, between the minimum visible and the minimum separable.

As with other faculties of the eye, no absolute and constant value can be given for the minimum separable. It varies greatly with several factors, viz., (a) the *intensity of illumination* of the test object, (b) the spectral character of the light, (c) the region of the retina stimulated and (d) the size of the pupil.

The resolving power of the eye for two points increases with the illumination, as illustrated in fig. 404. This is a fact difficult to explain. It might be thought that as long as the illumination was above the threshold for a just perceptible sensation, increase in the intensity of the light would be without influence upon the threshold for the minimum separable. Two theories which have been proposed to account for the phenomenon

FIG. 404. Relation between visual acuity and illumination. (After Hecht.)

will be mentioned, not because they give any final answer to the problem, but because they bring up some interesting points.

Hartridge proposes a theory based upon the aberrations of the optical system of the eye and the ability of the retina to discriminate between small differences of light intensity (p. 964). The retinal image is not clearly defined but is blurred by diffusion circles or bands, due to the diffraction of light at the pupillary margin and to colored fringes (chromatic aberration, p. 1000). Assuming the pupil to be 3 mm. in diameter and a foveal cone 3.2 mm. across, he made the following calculations of the light distribution on the retina caused by a white line separating two dark areas. The illumination of the row of cones corresponding to the center of the line image was taken as 100. The illumination of the next row was 31%, of the next 9%. The diffusion bands thus virtually increase the width of the image of the white line beyond that indicated by calculations from the visual angle, and encroach upon

the dark boundaries. The fine movements of the eyes are continually shifting the image and even the slightest movement will cause the line of junction between the outermost diffusion band and the dark area to move from one row of cones to another. A row of cones is therefore stimulated at one instant at a different intensity than at the next. If the difference in light intensity is greater than 10% it is appreciated, and thus a gap between the two dark areas is detected. Now the threshold for discrimination of differences in light intensity varies with the illumination (p. 965). Consequently, when the illumination is reduced the difference between the intensity of the outermost diffusion bands and of the dark areas is not perceived, i.e., the shift of the line of junction from one cone to the next causes no sensation. The difference between the illumination of the inner and outer bands may be still detectable, but the width of the bright line will be re-

FIG. 405. Statistical distribution of sensibility of rods and cones. The ordinates read directly in units of visual acuity. (After Hecht.)

duced. With further reduction in the illumination and the consequent raising of the threshold for intensity discrimination the white image becomes still narrower and finally, when the angular width is about 1", the dark areas fuse across it.

Hecht's theory postulates a change in the "grain" of the retina as a result of variations in illumination. The retina, according to Hecht, is made up of sensitive elements of different intensity thresholds distributed in a statistical manner similar to that of other populations. At low levels of illumination only a proportion of these elements (i.e., rods with the lowest threshold) are excited. The active elements are therefore farther apart and the "grain" of the sensitive surface is relatively coarse. As the light intensity increases the thresholds of more and more elements are exceeded. More rods function, that is, the number of active elements is increased and the "grain" of the retina is finer. As the illumination rises further, cones, first those with the lowest thresholds and later less sensitive ones, become active. The maximal effect of increasing the illumina-

tion upon the resolving power is reached when the entire rod and cone population is responding (see fig. 405). Objections to both of the theories just outlined could be cited; several observations indicate that the threshold for the minimum separable is not dependent entirely upon retinal factors but that central processes play an important part.

The resolving power of the eye is greater for monochromatic light than for a mixed light source such as daylight when the two have equal illuminating values. This fact is due to the absence of chromatic aberration in the former instance. Monochromatic yellow light (575 $m\mu$) gives the highest value, next in order come green, red and blue. Mercury arc light, owing to its greater homogeneity, gives higher values than ordinary white light.

Three factors are involved in the effect of pupillary size upon the resolving power of the retina. Increase in diameter allows more light to enter the eye and therefore increases the illumination of the retinal image and raises the visual acuity. Diffraction

FIG. 406. (After Adler.) See text.

tion is also reduced by widening the pupillary aperture which will tend to improve the definition of the image. On the other hand, narrowing the pupil diminishes chromatic aberration. The optimum pupillary size lies between maximum constriction and full dilatation, namely, at a diameter of about 3 mm.

With ordinary illuminations the visual acuity is some twenty times greater at the fovea than in any outlying part of the retina. In the dark adapted eye (p. 967) the peripheral retina has a much higher value than the fovea.

The illumination of the field surrounding the test object (the surrounds) has an important influence upon the resolving power of the eye. A uniform increase in the illumination of the surrounds up to $\frac{1}{10}$ that of the test object progressively increases visual acuity. Raising the illumination of the surrounds from this point to equality with the test object causes a slight reduction in visual acuity and, when the surrounds become brighter than the test object, there is a decided depression. A very bright but small light source situated in the neighborhood of the test object, e.g., a motor head light, causes a very marked lowering of the visual acuity. The effects caused by such concentrated

sources of light are referred to as "glare." If the surrounding light source is not too bright and especially if the surrounds are dark, little depressing effect upon the acuity of vision is produced, indeed there may be an improvement due to the accompanying pupillary constriction.

THE DISPLACEMENT THRESHOLD OR THE VERNIER ACUITY. These terms are applied to the visual faculty of recognizing a break in the continuity of a border, a variation in width of a line or the lack of alignment of two straight lines placed end to end. This power of the eye is some ten times greater than its ability to resolve two points. A break in a line subtending an angle as small as $5''$ or even $1''$ can be detected under optimal conditions. It seems quite certain that this visual faculty is not limited by cone diameter, for the break must lie on a single cone, and the lines on both sides of the break on the same row of cones (fig. 406). It is probable that the underlying mechanism is different from that governing the threshold for the discrimination of two points. For example, its threshold is only slightly raised by increasing the illumination (p. 963).

Anderson and Weymouth offer an interesting theory to account for the extraordinary accuracy of the vernier acuity. They suggest that the slight but continuous eye movements shift the line image over the retina, causing successive stimulus patterns. The averaging of the successive patterns gives a sense of position which they call *retinal local sign*. The longer the lines, the greater are the number of patterns presented to consciousness and, consequently, the more accurate is the averaging process. For details of the view of the authors the reader is referred to their original paper.

SOME PRACTICAL CONSIDERATIONS WITH REGARD TO LIGHTING. Besides reducing visual acuity, glare causes discomfort and one instinctively attempts to protect the eyes by closing the lids, raising the hand as a shield; the pupil constricts. A constant source of glare, even of mild degree, results in eye strain. Glare has been classified into three types—veiling, dazzling and blinding. *Veiling glare* is that due to strong light which, being uniformly superimposed upon the retinal image, reduces contrast. The light reflected from a printed page under a bright sky is an example. *Dazzling glare* is due to scattered light in the ocular media which does not form part of the retinal image (p. 1000). Such can be produced by a strong light shining into the eye from an angle of about 45° . *Blinding glare* results when one looks

directly at a very bright light. It is due to an actual reduction of retinal sensitivity.

For moderately fine work, such as reading, sewing, typesetting, etc., the illumination of the objects should not be less than from 10 to 20 foot candles. An illumination of 10 foot candles is efficient for reading ordinary black type on good paper, but the higher illumination is necessary if the printing or the paper is of poor quality. The effect of lighting upon the performance of typewriters, mail sorters and others engaged in fine work has been the subject of a number of investigations. Raising the illumination has been found to increase the rapidity and accuracy of the work from 10 to 16 per cent and to reduce eye strain and general fatigue. The maximum efficiency appears to be reached when the illumination is about 20 foot candles. The lighting should be diffuse, and naked bright light sources which would cause glare eliminated. The central field should receive additional lighting so that its illumination will be from 5 to 10 times that of the surrounds. The constant use of the eyes in poor lighting leads to ocular strain and fatigue with consequent headache. It may cause increase in pulse rate and even nausea; ultimately serious eye defects, especially in the young, may result. The quality of the light is also an important factor. Nitrogen light, being more homogeneous, has a higher visual acuity than the ordinary incandescent light bulb; the kerosene lamp lies between the two.

THE DISCRIMINATION OF DIFFERENCES IN LIGHT INTENSITY. This faculty was first investigated by Bouguer in 1760 and later by Weber (1834) and Fechner (1858). The latter observer found that when the light intensity is gradually increased the least change in illumination which can be perceived by the subject occurs in a series of steps. This relationship is expressed in the Weber-Fechner law which is applicable not only to vision but to other senses as well. The law states that the least perceptible difference between a series of stimuli is in each instance a certain constant fraction of the preceding stimulus. For example, let us suppose that for vision the constant is $\frac{1}{100}$ and the initial illumination is 100 candles. Then, if the light of one more candle is added, the difference in illumination will not be recognized; that is, the light of 101 candles is perceived to be greater than that of 100. If we were 1000 candles to start with, 10 more would need to be added before any difference could be noticed. If, therefore, the logarithms of the

intensities are plotted (abscissae) against the least perceptible differences in sensation (ordinates) a straight line should result. The law may be stated in another way, namely, that in order to cause a series of equal increments in sensation the strength of the stimulus must increase in geometrical proportion. Or again, the added intensity (ΔI) necessary to cause a just perceptible difference in sensation (ΔS) bears a constant ratio $\left(\frac{\Delta I}{I}\right)$ to the preceding intensity (I). Thus, $\Delta S = K \frac{\Delta I}{I}$.

When the logarithms of the light intensity are plotted against the just perceptible differences, the curve shown in fig. 407 is obtained. The curve is composed of three parts. It is only section A representing the relationship at moderate light intensities that accords even

FIG. 407. Curve of the intensity discrimination of light. (After Hecht.)

approximately with the Weber-Fechner law. At intensities below and above this limited range marked deviations from the law occur (sections B and C). The whole curve covers a range from the lowest intensity to one of dazzling strength and comprises 572 steps of just perceptible differences. Starting with the very lowest intensities, e.g., 0.0000484 millilamberts (I) the least absolute increment of the stimulus which is effective (ΔI) is very small (Koenig and Brodhun's data), namely, 0.0000316 millilamberts, and increases progressively as the intensity rises, so that at an illumination of 3.853 ml ΔI has a value of 147.0 ml. The fraction $\frac{\Delta I}{I}$, therefore, is not constant, nor does it show a continuous change in one direction, for it diminishes from about $\frac{1}{100}$ at the lowest intensity to about $\frac{1}{1000}$ at moderate ranges and then rises again to $\frac{1}{100}$ at the highest intensity.* Hecht considers that the low intensity part of the curve (B) represents rod func-

* Some recent observations indicate that this increase with higher intensities does not occur if the eye is fully light adapted, the fraction remaining at the lowest value even though the illumination is unpleasantly intense (see Craik).

tion and the high intensity portion (C), the activity of the cones. The cones are therefore more sensitive to *differences* in illumination than the rods, though their threshold for light perception (intensity threshold) is higher (p. 961).

INTERMITTENT RETINAL STIMULATION; FLICKER.

When the retina is stimulated intermittently by a series of light flashes as may be produced by interrupting a continuous light by a rotating notched disc or by reflecting light from a rotating disc divided into alternate black and white sectors, a characteristic flickering or unpleasant glittering sensation is experienced when the periodic stimulation reaches a certain frequency. Upon further increasing the speed of rotation and, in consequence, the frequency (number per second) of the light stimuli, fusion results and the flicker disappears to be replaced by a continuous sensation. The frequency at which this occurs is called the *critical fusion frequency* (C.F.F.). If the duration of the flashes at the instant of fusion be designated a and the length of the dark intervals between them designated b then the sensation produced is equal to that which would result from a continuous stimulus having the value $\frac{a}{a+b}$. This is known

as the Talbot-Plateau law. It accounts for the well-known fact that a gray sensation of any depth can be matched by throwing black and white images alternately and at a suitable frequency upon the retina. Similarly white and red images give, at the critical fusion frequency, a sensation of pink, blue and red a sensation of purple, yellow and green of yellowish green, and so on. These effects are simply explained by *visual persistence*, that is, the sensation evoked by one image has not passed off before the next one is produced, thus a blend of the two sensations in consciousness results.

The value of the C.F.F. is variable, depending upon several conditions the most influential of which is the intensity of the light, the value rising as the intensity increases. The influence of light intensity is embodied in the Ferry (1892)-Porter (1906) law which states that the *critical fusion frequency is directly proportional to the logarithm of the light intensity*. Thus $n = K \log I$,⁹ where n = flashes per second and I = illumination.

⁹ Determination of the C.F.F. furnishes an accurate and convenient method for comparing the brightness of differently colored lights. It is especially valuable in the comparison of the brightness of colored lights because of our natural tendency to confuse the brightness of a color with its hue or saturation.

The Ferry-Porter law is valid, however, only under certain special conditions; it holds over moderate ranges of illumination of the test object when the image is restricted to the fovea. Above and below this middle range the linear relationship between intensity and the critical fusion frequency does not hold. Porter, using a test object whose image fell upon the fovea and upon the surrounding retina as well, found that the intensity-C.F.F. relationship could be expressed by the formula $n = K \log I \times K^1$; the value of K is different for high and low levels of illumination. When the value of n is plotted against $\log I$ at low and at high intensities the points fall on two straight lines, one at low the other at high intensities. It is believed that these represent respectively rod and cone function, a conception borne out by the results of Hecht and associates and of Lythgoe and Tansley.

FIG. 408. Relation between critical frequency and $\log I$ for white light with a 2° field in four retinal locations; at the fovea, and at 5°, 15°, and 20° above the fovea. (After Hecht from Hecht and Verrijp.)

Hecht found that with a stimulus restricted to the fovea (cones) the relationship was linear for a middle range of illumination, but above this the curve flattened out; below, it formed a very gentle curve. With the image on extra-foveal regions the data form two intersecting straight lines, one at lower the other at higher intensities, the former presumably represents rod function, the latter peripheral cone function (fig. 408).

Lythgoe and Tansley observed that during dark adaptation the C.F.F. falls in both the fovea and the peripheral parts of the retina when the intensity of the test light was high (6.8 foot candles). At low intensities (0.020 foot candles) the C.F.F. also falls at the fovea, but rises in the peripheral retina. Now, as judged by other criteria, only cones are functioning at high intensities whether the fovea or the peripheral retina is being tested; at low intensities only rods. Also, it was found by Lythgoe and Tansley that when red light was used for testing (rods insensitive), and

a case of night blindness (defective rods) a fall in the value of the C.F.F. occurs during dark adaptation. The fall in the value with high illuminations of the test object is due presumably to the cones and the rise with low illuminations to the rods. At moderate illuminations of the test object a fall occurs during the first 5 minutes of dark adaptation (due to cones), see p. 958 followed by a rise (due to rods). The critical frequency due to the rods is highest with dark surrounds; that due to cones is increased by bright surrounds, the maximum being reached when the brightness of the latter and of the test object are equal.

A study of the retinal potentials (p. 973) during intermittent stimulation shows that when a light flash falls upon the retina during the "off effect" of a preceding stimulus, the *d* wave is interrupted and a pronounced negative dip occurs. This is an exaggerated *a* deflection (P_{III}). The negative deflection is followed by a large positive swing which, if the second stimulus occurs soon after the first, is simply the return of the momentarily interrupted "off effect" of the first. If the interval between the two is greater, the upswing

- (1) Dilatation of the pupil.
- (2) Increased sensitivity of the retina, i.e., lowering of the intensity threshold and of the thresholds for the minimum separable and the discrimination of intensity differences.
- (3) Purkinje shift (p. 958) towards the blue end of the spectrum.
- (4) Regeneration of visual purple in the rods.
- (5) Certain structural alterations in the retina (of cold-blooded animals) and a change in reaction from acid to alkaline (see p. 973).

In bright illumination the pupillary diameter is about 3 mm., but when the eye is shielded from light the pupil immediately commences to dilate and reaches a diameter of 8 or 9 mm. in full dark adaptation. In the dark adapted eye the first detectable response—slight constriction—of the pupil occurs at an illumination of about 0.025 meter candles.

The intensity threshold of the peripheral retina

FIG. 409. Electroretinogram recorded during intermittent stimulation. See text. (From Granit.)

is higher, and is then due to the *b* deflection (P_{II}) of the after coming stimulus. Thus, if the light flashes are so timed that each interrupts the "off effect" of its predecessor, a series of regular ripples appears in the electroretinogram which apparently are the cause of the flickering sensation (fig. 409). No negative dip occurs nor do the characteristic ripples appear if a flash falls upon the retina *before* the "off effect" of the preceding one—a continuous sensation should therefore result.

ADAPTATION OF THE EYE TO DIFFERENT LIGHT INTENSITIES

The retina behaves differently in partial darkness than in bright light. It has been pointed out elsewhere (p. 958) that this difference is attributed to the independent functions of the rods and cones.

DARK ADAPTATION. SCOTOPIC VISION. The phenomenon was first studied by Aubert in 1865. It is common experience that upon passing from light into darkness we become blind for the moment; but soon a faint glimmer of light appears and gradually more and more of the detail of our surroundings becomes visible. The adaptation of the eye to the low illumination is associated with the following changes.

commences to fall almost upon the instant that the eye is darkened, the fall being very rapid for the first 10 minutes. After this and up to 30 minutes, the fall in the threshold is less precipitous and from then on is very slow. For practical purposes the extrafoveal retina may be considered to have reached its maximum sensitivity after about 40 minutes in the dark, though a gradual slight increase occurs for several hours thereafter. The light sensitivity of the peripheral retina is increased by from 10,000 to 20,000 times by dark adaptation (fig. 410).

It has been doubted that dark adaptation of the fovea occurs; this is now conceded though it is of minor degree. When the eye is fully dark adapted the sensitivity of the fovea is only about $\frac{1}{1000}$ that of the extrafoveal retina. It is a familiar fact that in partial darkness an object may be seen "out of the corner of the eye" (peripheral vision) but is invisible when the eyes are turned to look directly at it (foveal vision). Foveal dark adaptation is very rapid, being almost complete within from 3 to 4 minutes. Hecht found that a small red cross (wave length greater than 650 m μ), to

which the rods are almost insensitive, was seen at a much lower threshold of illumination by the dark adapted eye. The threshold was found to fall from 450×10^{-4} ml. to 10×10^{-4} ml. in 30 seconds and to 3×10^{-4} in 20 minutes.

The color sense in the dark adapted eye. The rods are insensitive to color, and in the dark adapted eye their threshold to white light is very much lower than that of the fovea; therefore, a colored object with an illumination value around the threshold of the rods first appears without color. As the illumination of the object is increased its color is perceived when the threshold of the cones is reached. The interval between the two thresholds is called the *colorless (achromatic) interval*. There is no colorless interval for red, since the rods (like the photographic film) are insensitive to this color (λ greater than $650 \text{ m}\mu$). In other words a red object appears black in a very dim light and is detected with difficulty against a dark background; not until the intensity of its illumination reaches the threshold of the cones is it perceived. In red light, therefore, dark adaptation of the rods is not prevented. The achromatic interval is shortest for blue. In severe instances of night blindness the Purkinje shift and the achromatic interval for all wave lengths are absent; this is what one would expect to result from the rod defect.

LIGHT ADAPTATION. PHOTOPIC VISION. The dark adapted eye is dazzled by even moderately bright light, but adaptation to the higher illumination develops rapidly. During light adaptation changes opposite in nature to those occurring in darkness take place, namely,

- (1) Constriction of the pupil.
- (2) Diminished sensitivity of the retina.
- (3) Purkinje shift towards the red end of the spectrum.
- (4) Bleaching of visual purple.
- (5) Shift in reaction of the retina from alkaline to acid and structural changes, in certain species (p. 973).

The eye adapts much more readily to light than to darkness. In its measurement the threshold at full adaptation is first determined; the eye is then exposed to bright light for a certain period after which the light is switched off and the threshold found before any appreciable degree of dark adaptation has developed. This procedure is repeated for different time intervals following the preliminary period of dark adaptation. It is found that the greatest decrease in sensitivity occurs during the first 20 or 30 seconds; this is followed by a gradual fall for a period of 10 minutes. After this time light adaptation may be taken for practical

purposes to be complete, though some slight reduction in sensitivity occurs up to 30 minutes.

THE PERCEPTION OF MOVEMENT. This is the most primitive of the visual functions; in disease it is the last to fail and is the first to return should any improvement in vision occur. The peripheral (extrafoveal) retina is a specially differentiated organ for the perception of movement (Exner), being much more sensitive in this respect than the fovea. It is a familiar fact that a slight movement is more readily detected if the moving object

FIG. 410. The course of dark adaptation. The lower portion of the curve is redrawn in the inset on a magnified scale of ordinates. The exceedingly great change in the intensity during the first 10 minutes is clearly seen. (After Hecht, *J. Gen. Physiol.* 1922, 503.)

FIG. 411. Illustrating irradiation.

is not in the direct line of vision, i.e., when the image falls upon the peripheral retina, than when the eyes are fixed upon it. The most sensitive part of the retina is from 10° to 15° from the fovea but diminishes progressively towards the periphery. In the region of maximum sensitivity the angular velocity of a just perceptible movement is from one half to one minute per second, provided that there are stationary objects in the visual field to serve as reference points. When such are absent the angular velocity must

from 10 to 20 times as great in order for the movement to be perceived. On the other hand, if the angular velocity is very great the movement is not perceived; owing to visual persistence a very rapidly moving object appears as a stationary streak. The total distance travelled, i.e., the displacement of the object, as well as the angular velocity is, of course, a factor in movement perception. The minimum displacement is about 17 seconds of arc, under optimal conditions. The sensitivity of the retina to movement is lower in the dark adapted than in the light adapted eye.

When the eyes are stationary but the body or head is moved an *apparent* movement is given to objects in the visual field. When travelling in a train, for example, near objects appear to move in the opposite direction to the direction of travel, while those in the background appear to move with the moving vehicle. Apparent movements of surrounding objects also occur when the eye is displaced slightly by pressure upon it with the finger tip, or as a result of involuntary contraction of the eye muscles. These apparent movements are attributed to the successive stimulation of groups of receptors as the images move over the retina. When the eyes are moved voluntarily from one object to another in the visual field, images must sweep over the retina in a similar fashion, yet there is no apparent movement of stationary objects.¹⁰ Conversely, the movement of an object is perceived when it is followed by the eyes, though the position of its retinal image does not alter. It is quite evident that the perception of movement is very complex and cannot be explained in all its

aspects upon physiological grounds. It is suggested that the absence of an apparent movement of stationary objects when the eyes are turned from one part of the visual field to another is to be explained upon the basis of *attention*. The attention exercised by the observer in changing the fixation of his eyes from the one to the other point compensates, it is believed, for the movements of the images over the retina. In other words, the successive stimulation of visual receptors is ignored because the point to which the eyes are to be turned engages the attention at the moment that the eye movement takes place, or even before. The perception of the movement of an object pursued by the eyes must also depend upon cerebral processes.

Apparent movement is also produced by the stimulation of closely approximated retinal areas in rapid succession by a series of images of a stationary object. The two main factors determining this so-called *stroboscopic illusion* of movement are the time interval between the stimuli and the *angular separation* of the successive retinal images. A visual sensation of smooth motion is produced when the angular separation is about 1 degree or less and the intervals between the stimuli about $\frac{1}{10}$ second. At intervals of $\frac{1}{30}$ second or less no sensation of movement is produced. The illusion of motion is also lost if the time intervals are lengthened to $\frac{1}{2}$ second or greater, the impressions then becoming discreet.

Irradiation. Owing to chromatic and spherical aberration the images on the retina are not formed of geometrical points of light, but rather of bright points surrounded by diffusion circles. For this reason, and also probably as a result of the spread of the effect of the stimulus (*irradiation*) to neighboring neural elements of the retina, or even within the visual area in the brain, a bright area on a dark ground appears larger than a dark one of the same size upon a bright ground. In either instance the bright area encroaches upon the black area (see fig. 411).

¹⁰ An allied phenomenon and one which offers a similar problem to be solved is seen in cutaneous sensation. We are able, for example, to distinguish between the movement of the finger over a stationary object and the movement of an object over a motionless finger. In both instances receptors are stimulated successively.

CHAPTER LXXV

THE NATURE OF RETINAL PROCESSES; OBJECTIVE RETINAL PHENOMENA; COLOR VISION

THE NATURE OF THE RETINAL PROCESSES

The photochemical mechanism of vision. Visual purple or rhodopsin is a rose-red photosensitive pigment found in the outer segments of the rods; it has not been demonstrated in the fovea. The pigment was discovered by Boll in 1876 and extracted from the retina by Kuehne in 1878. Its presence is essential for normal vision in dim light, and to it the nervous layer of the fresh retina, detached in the dark from the pigment layer, owes its reddish color (p. 956). It can be extracted from the retina by bile or a solution of bile salts, but the most effective extracting agent is digitonin. Visual purple either *in situ* or in solution is bleached by white light or by light of any wave length between 385 m μ and 650 m μ . Maximal bleaching is caused by green light with a wave length of about 502 m μ . In the living animal, and also to some extent in solution, the pigment regenerates in darkness. Chase's experiments suggest that another photosensitive substance in association with visual purple is necessary for regeneration. This associated pigment is particularly sensitive to blue light. The regeneration process is not affected by section of the optic nerve, but the drug santonin retards it, and in large doses causes yellow vision and night blindness. When one eye is illuminated, the other being shaded, bleaching of rhodopsin occurs only in the former.

If the eye of a rabbit is excised in darkness or in red light (light of a wave length greater than 650 m μ does not bleach the visual purple) and then exposed to an object clearly defined in light and shade, e.g., a window sash against the sky, an image of the object will be found to have been impressed upon the retina when it is examined in the dark room. The image is caused by the bleaching of the visual purple where the bright parts of the image fell upon the rods. The retina thus behaves like a photographic film; the image so obtained is called an *optogram* (see fig. 412).

Our knowledge of the chemistry of rhodopsin has been greatly advanced within recent years. It is a complex conjugated protein containing a carotenoid pigment as a prosthetic group. Its molecular weight has been variously estimated from 100,000 to 800,000. A value of 270,000 was ob-

tained by Hecht and Pickels. In solution or in the retina visual purple is bleached by intense light, first turning orange in color which changes rapidly to yellow and finally becoming 'colorless'. According to Wald, rhodopsin breaks down during bleaching into protein and an orange-yellow carotenoid pigment which he calls *retinene*.¹ Retinene is extractable by chloroform in which it shows a broad absorption band maximal at 387 m μ . In antimony chloride it shows maximal absorption at 664 m μ . The final colorless product is vitamin A. An extract of completely bleached retinas, therefore contains no rhodopsin but is rich in the vitamin. Under physiological conditions, vitamin A does not accumulate in the retina but is carried away in the circulation. Regeneration of rhodopsin from vitamin A occurs in the retina of the living animal during dark adaptation.

The rhodopsin vitamin A cycle is shown in the following scheme, modified from Wald.

¹ Lythgoe has given the name *transient orange* to the first product of the bleaching process and *indicator yellow* to the second derivative. This latter, as its name implies, behaves like an acid-base indicator, being chrome yellow between pH 3.3 and 4.0, a deep lemon yellow at neutrality and a pale lemon between pH 9.3 and 10.0. Indicator yellow is also formed immediately from rhodopsin by heat and by the action of acids and alkalis. The mixture of yellow pigments formed during bleaching was called "visual yellow" by Kuhne.

² The photosensitive pigment in the retinas of fresh water fish differs from that found in the retinas of most vertebrates including the marine fishes. This pigment, which is truly purple in color, has been named *porphyropsin* by Wald. It follows a retinal cycle identical with that of rhodopsin except that vitamin A₂ takes the place of vitamin A(A₁), and the retinene produced during bleaching has, in chloroform, an absorption band with a maximum at 405 m μ instead of at 387 m μ . Wald has made the highly interesting observation that the type of pigment present in the retinas of the euryhaline fishes (those species which migrate from salt to fresh water or vice versa) is determined largely by the waters, salt or fresh, in which they are spawned. Thus, in fish, such as salmon, which spawn in fresh water (anadromous forms) the predominant pigment is porphyropsin, whereas, in those, such as, the fresh water eel which spawn in the sea (catadromous forms) rhodopsin predominates.

(328 $m\mu$ in chloroform)	(387 $m\mu$ in chloroform)
(615 $m\mu$ in antimony chloride)	(664 $m\mu$ in antimony chloride)

In the completely bleached isolated retina or in the intact eyes of animals fed upon a diet deficient in vitamin A, regeneration of rhodopsin cannot take place, though in the former some regeneration from retinene may occur in darkness. It will be recalled that vitamin A deficiency is one cause of night blindness (hemeralopia).

Convincing evidence can be cited for the view that the first phase in the retinal process whereby radiant energy is converted to nerve impulses (electrical energy) is photochemical in nature.

FIG. 412. Optogram of a window in a rabbit's eye. The white rectangular area is a layer of colorless medullated nerve fibers and the circle at its center is the optic disc. (From Howell after Kuhne.)

FIG. 413. Electroretinogram. (From Granit, re-drawn.)

There can be little doubt that rod vision is dependent upon such a process and that the photochemical pigment, rhodopsin plays an essential rôle in twilight vision. When the absorption spectrum of this pigment is plotted (reciprocals of the minimum energy required for bleaching along the ordinates, and the wave lengths along the abscissae) the graph is found to be identical in shape with the visibility curve for twilight vision (fig. 416). A curve formed by plotting the rate of bleaching of visual purple against the wave length coincides almost exactly with the absorption curve; in other words, visual purple follows Draper's law which states that chemical change is produced in a photosensitive material only by those waves which are absorbed. The significance of these facts is unmistakable.

Though the visibility of the dark adapted eye and the absorption curve of visual purple are identical in *shape*, there is a difference of 7 $m\mu$ in the maxima of the two curves, the maximum of the former lying at 510 $m\mu$ (Hecht and Williams), that of the latter at about 503 $m\mu$. An explanation for this discrepancy will be offered presently. The retina also obeys the Bunsen-Roscoe law formulated for photochemical processes in general, namely, that for the production of a given photochemical effect a constant quantity of energy is required which can be distributed within certain limits by varying either the illumination or its duration. In other words, the product of the

FIG. 414. Analysis of composite retinal electrical response (cat's eye) at two intensities, 14 ml. and 0.14 ml. and area of 1661 sq. mm., viewed at a distance of 70 mm. Components, broken lines. Composite curve drawn in full. The *a*-wave is broadened slightly out of scale to show its derivation more clearly. (Granit, *J. Physiol.*, Vol. LXXVII, 1933.)

FIG. 415. Curve of frequencies of impulses in optic nerve. (After Adrian and Matthews.)

illumination (*I*) and the time of exposure (*T*) is constant, $\text{Energy} = kIT$.

The difference between the maxima of the absorption curve of visual purple and the twilight visibility curve is actually somewhat less than that given above. Dartnall and Goodeve point out that the visibility curves should be plotted using an equal quantum spectrum (the quantum of light energy varies with the wave length) and not an equal energy spectrum (p. 958). When this is done the maximum of the twilight visibility curve is at 506 $m\mu$ or 507 $m\mu$. A difference therefore of only 4 or 5 $m\mu$ exists between the maxima of the two curves. In the recent experiments of Lythgoe with purified preparations of visual purple maximum absorption was obtained at 502 $m\mu$. Hecht and Williams have pointed out that a discrepancy of even 7 $m\mu$ may well be accounted for

by the fact that the absorption curves of rhodopsin have been determined of necessity upon *solutions* of the pigment and some difference should be expected between curves so obtained and the absorption of visual purple as it exists in the retina.

Important evidence for the photochemical nature of the initial stages of the visual process has been obtained by Hecht through the study of a much simpler photochemical mechanism, namely, that afforded by certain invertebrate forms. The body surface of a clam, *Mya*, of an ascidian, *Ciona*, and of a mollusc, *Pholus*, possesses light sensitive areas. When exposed to light the syphons of *Mya* after a long latent period become retracted. Several points of similarity between this reaction, which is undoubtedly photochemical in nature,

FIG. 416. Relation between absorption spectrum of visual purple in bile salts solution (monkey and rabbit) and absorption spectrum of sensitive substance in the rods as given by the visibility curve of figure 400. Though the two curves are identical in form, the visibility curve is shifted 7 or 8 $\mu\mu$ toward the red. (After Hecht.)

and vision have been demonstrated. *Mya* shows light and dark adaptation, its sensitivity being increased in the dark and reduced by a stay in daylight. The reaction follows the Bunsen-Roscoe law; and the Weber-Fechner law is obeyed over a limited range of moderate light intensities, the ratio $\frac{\Delta I}{I}$, as in the case of the retina, increasing at high and at low intensities. The reaction also shows selective spectral sensitivity, the energy required to elicit a response varying with the wave length.

The photochemical theory, though satisfactory for rod vision, failed to explain daylight vision, for no photosensitive pigment had been demonstrated in the cones of the mammalian retina. Nevertheless, as a result of his studies, Hecht had thought it highly probable that foveal vision was also dependent upon a photochemical mechanism. The visibility curve of the light adapted eye is

identical in *shape* with that for twilight vision and consequently with the spectral absorption curve of a solution of visual purple. But the *maxima* of the three curves do not coincide; that of the light adapted eye being at 550 $m\mu$. The identical shapes of the curves, nevertheless, suggest very strongly that cone vision is also dependent upon a photochemical substance—possibly visual purple in high dilution. A low concentration of the pigment in or around the cones would account for its not being evident; yet its function would not necessarily be abolished thereby, for it has been shown that certain photochemical substances, e.g., silver nitrate and cyanin, do not lose their properties when spread in very thin films. However, the difference between the maximum of the daylight visibility curve and that of the absorption curve (about 45 $m\mu$) were considered too great to be accounted for purely upon the basis of changes in the properties of the pigment during its extraction.

The results of Wald's researches have largely resolved the difficulty of extending the photochemical theory to cone vision. He extracted the dark-adapted retinas of chickens which contain chiefly cones. Such an extract would contain rhodopsin derived from the small rod population mixed with cone pigment if such existed. Upon exposing the extract to red light, to which the rods are only slightly sensitive, bleaching occurred, absorption being maximal at 575 $m\mu$. Subsequent exposure of the extract to white light caused bleaching characteristic of rhodopsin with maximal absorption around 508 $m\mu$. The initial bleaching by red light was due, presumably, to a photosensitive pigment derived from the cones. The spectral properties of this pigment indicate that it is violet in color. Wald has therefor named it *iodopsin*. A comparable pigment has been obtained by Chase from the retinas of frogs. The maximal sensitivity of chicken cones is at 580 $m\mu$. and that of the rods at about 520 $m\mu$. The former figure is in close agreement with the maximal absorption (575 $m\mu$.) of iodopsin.

The following expression has been used by Hecht to illustrate the photochemical reaction:

light

$S \xrightarrow{\text{light}} P + A$, where S is the photosensitive substance which breaks down into P and A in the light; these in turn are built up into S in the dark. The two opposing reactions proceed simultaneously, the velocity in either direction depending upon the intensity of the light and upon the concentrations of S and of P + A. Provided that there is a sufficient supply of S, a certain

dark

quantity of absorbed light energy causes a constant quantity to be decomposed. When the dark adapted eye, in which visual purple (S) is in high concentration, is exposed to light the reaction proceeds rapidly to the right until equilibrium is established, light adaptation is then complete. From then on, synthesis and decomposition proceed at equal rates and the concentrations of S, P and A are maintained at constant levels, so long as the light intensity does not alter. In darkness the reaction proceeds to the left, rapidly at first but then more slowly as the equilibrium point is approached. At full dark adaptation equilibrium is again established.

The decomposition products of the primary photochemical reaction $S \rightarrow P + A$ are supposed to catalyze a secondary chemical reaction whose products are immediately responsible for stimulating the afferent nerve terminals

NERVOUS MECHANISMS. The photochemical mechanism constitutes the means whereby light energy, through the breakdown of rhodopsin, causes a visual stimulus to be produced. But this is merely a preliminary phase in the retinal process which is essentially nervous in nature. It must always be borne in mind that the retina is an outgrowth of the brain. Functionally it is a "true nervous center" (Cajal). Unlike any other sense organ its receptors are in close association with synaptic connections, and many of the phenomena of the retina are expressions of interaction between neurons. For example, phenomena which have already been described for nervous centers, e.g., spatial and temporal induction, inhibition, rebound, etc., have been demonstrated for the retina. Adrian and Matthews demonstrated spatial summation, using the shortening of the latency of the optic nerve discharge as the criterion of increase in the retinal response. They found that as compared with the illumination of a single area simultaneous stimulation of four separate retinal areas caused a marked shortening of the latent period. Granit and Davis have shown by means of the electroretinogram the occurrence of temporal summation in the human retina. They found that when the retina is stimulated by two subliminal stimuli separated by an interval of about 50 m.sec. summation to the threshold results. The effect of the first stimulus persists, though gradually declining, for 135 m.sec.; after this interval, a second stimulus produces no response unless it is of threshold value itself. The retina, then, must not be looked upon simply as a mosaic of separate points each connected to the nervous system by its own nerve fiber and acting independently of the rest (Adrian and Matthews).

OBJECTIVE RETINAL EFFECTS CAUSED BY LIGHT STIMULI

Illumination of the eye causes (a) bleaching of the visual purple, (b) alteration in reaction of the retina from alkaline to acid, (c) histological changes in the pigment cells and cones of certain cold-blooded species, and (d) changes in electrical potential.

Little is known of the chemistry underlying the production of acid in the stimulated retina, but the acid is probably lactic derived from the breakdown of glucose, for it has been shown that the retina as compared with other tissues has a strong glycolytic action. The acidity increases with the intensity of the stimulus and is greatest with yellow-green light.

Histological changes in the retinas of frogs, fish and certain other cold-blooded forms occur upon stimulation, but have not been demonstrated in mammals. They consist of movements of the pigment granules of the cells of the outer retinal layer (p. 956) and retraction of the bases of the cones from the pigment cells, leaving an interval between the two. The contraction of the cones is apparently a reflex phenomenon, for it occurs upon stimulation of the opposite eye or even, according to some, upon exposure of the skin to light. Swelling of the rods in bright light, and then shrinkage in the dark so that they become separated by a distance of from 0.5μ to 0.8μ are other retinal phenomena seen in these species.

RETINAL ACTION CURRENTS; THE ELECTRO-RETINOGRAM. When the cornea and the optic nerve or the posterior pole of the darkened eyeball are connected through a galvanometer, a current is set up (*demarcation current*) with the cornea as the positive pole. A steady deflection of the galvanometer results. The cause of this current is not clearly understood. When a light is thrown into the eye a series of potential changes is produced which can be recorded as a corresponding sequence of waves. These are the retinal action currents, the record is called an *electroretinogram*.

Holmgren, the Swedish physiologist, was the first (in 1866) to demonstrate retinal action currents when the eye is stimulated by a beam of light. From then to the beginning of the present century they were studied by a number of investigators, including Dewar and McKendrick, Waller and Gotch. They were recorded with the string galvanometer by Einthoven and Jolly in 1908 and by Piper, by means of the capillary electrometer, in a series of studies from 1908 to 1911. In recent years with the development of more delicate methods of recording the subject has been reinvestigated by Chaffee, Bovie and Hampson, by Hartline and by Granit and his associates.

In the earlier experiments records were obtained from the surviving excised eye, and in many instances after removal of the anterior half of the globe, or from preparations in which dissection had caused a considerable degree of trauma. Though it was necessary to place one electrode directly upon the retina in order to prove the retinal origin of the currents,³ better results can be obtained by leaving the eye in situ and placing one electrode upon the cornea of the illuminated eye and the other (indifferent electrode) upon the eye of the opposite side or upon any moist surface of the body. Typical electroretinograms are obtained in this way. Hartline has applied this method to the human subject by means of water-tight goggles fitted to the eyes and filled with a 0.9% saline. The goggle in front of the eye to be illuminated holds the differentiated electrode and is fitted with a convex lens to correct for the optical effect of the solution. The indifferent electrode is fitted into the other goggle. In another method employed by Hartline for man, a cotton-tipped electrode is applied directly to the illuminated eye after anesthetization with a 2% solution of holocaine; the indifferent electrode is placed in the mouth.

The most satisfactory preparation from which to record the electroretinogram is the decerebrate animal, since perfect immobilization is thus secured, as well as full pupillary dilatation. The indifferent electrode is placed upon brain tissue on the proximal side of the decerebration cut, and the other electrode on the cornea. The recording instrument most commonly employed is the string galvanometer or some type of oscillograph, the currents being first conducted through a valve amplifier.

Analysis of the record. The electroretinogram (see fig. 413) consists of four waves, designated *a*, *b*, *c* and *d*. The *a* wave is a small, rapid negative deflection—a sharp notch below the base line—which appears after a short but variable latent period. The wave *b* is a well-marked positive deflection of about 8 millivolts, and *c* is a slow, prolonged positive wave which declines gradually though the eye remains constantly illuminated. The *d* deflection is a small positive change which appears after a brief latency when the light is cut off; for this reason it is usually referred to as the “off effect.”

Einthoven and Jolly concluded from an analysis of their records that the “on effect” (*a*, *b*, and *c* waves) was a composite deflection due to the algebraic summing of the potential changes of three separate retinal processes. The recent researches of Granit and his associates have confirmed and extended the work of these earlier investigators. The three processes have been designated *P*, *P_{II}* and *P_{III}*, since they can be

³ A characteristic record is not obtained after removal of the nervous layers of the retina.

made to disappear in this order by corresponding degrees of anesthesia. *P_I* is responsible for the sustained potential of the *c* deflection; it is abolished by light anesthesia, leaving the fast initial waves (*a* and *b*) unchanged. With deeper anesthesia the *b* wave becomes smaller and then disappears, leaving the component responsible for the *a* deflection. This is a prolonged negative deflection (see fig. 414).

In the final stage of anesthesia the negative component disappears and the retina, having apparently suffered an irreversible change, cannot be made to respond again. The *P_I* component is only seen at high light intensities and in the dark adapted eye; *P_{III}* is also absent, as a rule, at low levels of illumination. *P_{II}* is abolished by asphyxia. Thus, by varying the illumination, by anesthesia or asphyxia, records can be obtained composed of *P_{II}* + *P_{III}*, of *P_I* + *P_{III}*, of *P_{II}* alone or of *P_{III}* alone.

The three processes responsible for the electrical changes in the retina arise in the nervous layers and the potential changes do not represent nerve fiber responses since they cannot be obtained by placing the differentiated electrode upon the optic nerve entrance; *synaptic connections are essential for their production*. The *b* wave, for example, increases in amplitude with the illumination intensity; whereas, as will be seen presently, the magnitude of the action potentials of the optic nerve does not vary with the strength of the stimulus. Furthermore, the latency of the retinal response diminishes as the intensity of the light or the size of the illuminated area on the retina increases—additional evidence of synaptic transmission.

P_{III} (component responsible for *a* wave) is, according to Granit, an inhibitory process. *P_{II}* (responsible for *b* wave) is excitatory in nature and is followed by a discharge of impulses in the optic nerve. *P_I* (component causing *c* elevation) is not associated with a discharge of impulses in the optic nerve. The “off effect” (*d* wave) is considered to be a rebound phenomenon (p. 813) resulting from the cessation of the inhibitory process *P_{III}* and the release with consequent enhancement of the slower processes *P_I* and *P_{II}*, particularly of the latter.

ACTION POTENTIALS IN THE OPTIC NERVE. The action currents in the optic nerve of the conger eel were investigated by Adrian and Matthews. The optic nerve of this species is unusually long and contains relatively few fibers—facts of considerable technical advantage. The potentials were recorded by a capillary electrometer after passage through a four valve amplifier.

The nerve is almost “quiet” in the dark but a light flashed into the eye causes a discharge of impulses. If the nerve is crushed between the eye and the recording electrodes no potential waves appear. The total response to a flash lasts for about 15σ. Depending upon the intensity and

area of illumination, the latent period varies from 0.1 to 0.5 sec., becoming shorter with increasing strength of stimulus. The frequency of the impulses show two maxima, one (300 per sec.) associated with the "on effect" of the electroretinogram, the other with the "off effect" (see fig. 415).

The amplitude of the impulses (action potentials) or their grouping does not vary with the intensity of the stimulus or with the area of the retina illuminated (p. 786). On the other hand, an increase in either of these factors increases the impulse frequency and shortens the latency of the nerve response. Hartline has recorded the responses of a single optic nerve fiber and also finds that a change in frequency of the impulses, but not in their amplitude, results from varying the intensity of the stimulus. The effect of varying the area is limited to images under 1 mm. in diameter, the greatest effect being observed with variations in the size of images of 0.3 mm. in diameter or less. Though, as just stated, the latent period (i.e., the time elapsing from the application of the stimulus to the appearance of the first impulse in the nerve) is variable, the retinal nerve time (i.e., the interval between the *a* deflection of the electroretinogram and the commencement of the impulse discharge in the nerve) is constant with varying strength of stimulus. Variations in latency of the nerve response are therefore due simply to corresponding variations in the latent period of the retina.

As mentioned above, Granit's analysis of the retinal response shows that process II alone is responsible for the initiation of a discharge in the nerve. The impulses therefore reach their maxima where this process causes the *b* deflection and at the "off effect" (*d*) where rebound occurs as a result of the cessation of the inhibitory process (PIII).

The burst of impulses at the "off effect" is of special interest; such is not seen in the nerve fiber of any other receptor organ. Its significance, however, seems clear. The signalling of darkness to the centers in the brain is of just as great importance in the life of the animal as the signalling of light. A shadow or a dark object in the field of vision may indicate food or the approach of an enemy.

The decline in frequency of the impulses, i.e., between the two maxima, though the stimulus persists is difficult to explain. It might be attributed to sensory adaptation (p. 806). Yet how can such an explanation be reconciled with our own sensations, for, as a rule, an object at constant intensity of illumination does not appear less bright while we continue to look at it. On the other hand, it is certainly true that a moving image, which stimulates groups of retinal elements successively, is seen more easily and is more likely to attract

attention than a stationary one. Indeed in many species an immobile object apparently is not perceived. Is it that in the *intact* and *conscious* animal, a sustained sensation of brightness of a stationary object under constant illumination is due to the incessant involuntary eye movements which, by causing successive stimulation of groups of retinal elements, nullify the effect of adaptation and that the optic nerve transmits a continuous stream of impulses at high frequency?

COLOR VISION

Color perception is a function of the light adapted eye (p. 968); being entirely dependent upon the cones. Animals whose retinas contain only rods are therefore completely color blind. When the illumination of the field of vision is gradually reduced, red objects first lose their color, then those colored yellow, green or blue, in this order, become colorless. In dim light the surroundings are almost without color, being seen in shades of gray, black and a bluish white. The blue color of deep twilight is believed to be a peculiar function of the rods. Color possesses three qualities or attributes—hue, brightness and saturation.

Hue or *tone* is dependent entirely upon the wave length of the rays. Thus, red, yellow, green, blue and violet are different hues.

Brightness (*brilliance* or *luminosity*) is determined by the intensity of the rays,⁴ whatever their wave length, falling upon the retina. Thus, there can be many degrees of brightness within a single hue. Of two objects having the same hue and illuminated to the same degree, the one which absorbs the smaller proportions of the rays of the specific wave length and reflects the greater proportion appears the brighter. The different brightnesses of a given hue may be compared to a number of mixtures of black and white made up in various proportions to produce a graded series of shades of gray. For example, just as any shade of gray may be produced by adding black to white, so a paint of a given hue can be reduced to any degree of brightness by mixing with it a suitable quantity of black. It is very difficult for one to match the brightness of two different colors (heterochromatic photometry). The method mentioned in footnote p. 966 is resorted to, which overcomes the natural tendency to confuse brightness with hue and saturation.

Saturation (or *purity*). As in the case of brightness, color saturation may show infinite variations in degree within a given hue. Red is a more saturated color than

⁴ It might be more strictly correct to say "intensity of sensation" rather than "intensity of the rays" for we have seen that dark adaptation causes a shift in the point of maximal luminosity, but as measured physically of course no shift occurs.

pink. The difference is due to the relative quantities of white light with which the red light is mixed. For example, the saturation of a paint of a given hue can be reduced by mixing white with it. The mixture reflects white light as well as light of the wave length by which its hue is perceived. The saturation of a colored light could be readily determined by means of the spectroscope. Thus, a fully saturated red or green (homogeneous or monochromatic) light would give a red or a green color at the corresponding part of the spectrum, whereas, if either color contained an admixture of white light, all the spectral colors would appear, their intensity depending upon the quantity of white in the mixture.

THEORIES OF COLOR VISION

None of the many theories of color vision is capable of accounting for all the observed phenomena, either of normal vision or of color blindness. The theory suggested by Young (1807) and supported with extensions and elaborations by Helmholtz (1853) is the best known, the simplest and perhaps open to the fewest objections.

THE YOUNG-HELMHOLTZ THEORY. Though scarcely necessary it may perhaps be an advantage to recall some elementary principles. White light is a combination of light rays of wave lengths from about $720\text{ m}\mu$ to $350\text{ m}\mu$, and can be split into its constituent colors—red, orange, green, blue and violet—by means of a glass prism. These spectral colors can be recombined again to produce white light of the *same intensity* as the original light from which they were derived (Abney's law). It is not necessary, however, for one to use all these colors in order to produce white; only three, namely, red, green and blue (or violet) combined in suitable proportions, are required to produce white or any other color we may desire. Red, green and blue (or violet) are therefore called the *primary colors*. But pure spectral lights, not pigments, (see footnote p. 981) must be employed in the combinations. If we should set up three lanterns, of which one emitted red light, another green and a third blue (or violet), then by throwing one upon a screen or a blend of two or of all three, we could produce any color of light we chose as well as white. Red and green would give rise to yellow, red and blue or violet to purple, and so on; all three colors, mixed in equal proportions, would produce white. These are uncontested facts to which any theory of color vision must conform.

The Young-Helmholtz theory claims that there are three types of percipient elements in the retina, each containing a substance which is acted upon by one or other of the primary colors. The sensa-

tion of white and of the many different colors is due to the stimulation of the three elements at different relative intensities (see fig. 417). Pure red light for example, stimulates strongly those cones containing the "red substance" and the other types very feebly; green, blue or violet lights stimulate powerfully those containing the green, blue or violet substances, respectively; the sensation of white results when all three types are stimulated equally.

It is evident that this theory is in accord with the established facts in respect to color mixing. It also gives a plausible explanation of the common types of color blindness on the assumption that one or other type of cone is defective or lacking. For example, failure to appreciate red would be due to deficiency of the red-sensitive substance, absence of sensitivity to

FIG. 417. Diagram of three primary color sensations. 1 is the so-called 'red,' 2 'green,' and 3 'violet' primary color sensation. R, O, Y, etc., represent the red, orange, yellow, etc., colors of the spectrum. The diagram illustrates, by the height of the curve in each case, how the several primary color sensations are respectively excited to different extents by vibrations of different wave-lengths. (After Helmholtz.)

green to lack of the green substance. Temporary partial color blindness can be produced by intense stimulation of the retina by one of other of the primary colors, which is readily explained upon the basis of fatigue of the corresponding type of sensitive element. For example, if one looks at the sun for a couple of minutes through a red glass and then directs the eyes to differently colored objects, the perception of red is found to be lost—red geraniums appear black, yellow flowers green and pink roses sky blue (rose color being a blend of pink and blue). The eye fatigued in a similar way by green light sees the foliage colored bluish or reddish gray.

The theory fails, however, to explain the absence of color sense in the most peripheral part of the retina (p. 968). For if the sensation of white is due to the equal stimulation of three types of retinal receptor (which, according to the theory, must therefore be present in this part of the retina), why does not a sensation of color result when the

different types are stimulated unequally, as by red, green or blue? For the same reason the theory fails to explain complete color blindness (p. 980); nor does it fit the duplicity theory, or account satisfactorily for positive after images (p. 982). An objection which will be mentioned presently (but which really seems beside the point) is in respect to the claim that yellow is as much as a unitary sensation as either of the three so-called primary color senses.

Hering's theory (theory of opponent color pairs). This theory postulates the existence of three substances in the retina which give rise to three pairs of elementary and antagonistic sensations, namely, those of *yellow* and *blue*, *red* and *green*, and *black* and *white*. One sensation of each pair—*yellow*, *red* or *white*—is due supposedly to the breakdown—*catabolism* or *dissimilation*—of a corresponding hypothetical color-sensitive substance. The other member of the pair—*blue*, *green* or *black*—results from synthesis of the respective substance—*anabolism* or *assimilation*—Thus:

The theory offers a plausible explanation of successive contrast and negative after images (p. 982). A red or yellow light, for example, causes a green or a blue after image, respectively. The red (or yellow) image causes presumably, through catabolism, the reduction of the red-green (or yellow-blue) substance, which upon withdrawal of the light will undergo more rapid synthesis and, as a consequence, the opposite sensation of green (or blue). The theory fails however to explain satisfactorily positive after images. There is a certain psychological basis for grouping the six sensations into antagonistic pairs, as was emphasized by Hering, and by Goethe before him. It is pointed out that yellow, red and white are warm, bright and cheerful; blue, green and black are cold, dull and sombre.⁶

It will be noticed that this is a tetrachromatic theory, yellow being assumed to be a primary sensation like red, blue and green, and not, as in the Young-Helmholtz theory one compounded of red and green. Justification for this supposition is drawn from psychological considerations. Pure yellow, it is pointed out, is a sensation just as unitary as any one of the other three colors, for like them, no other color appears to be blended in it. We can see the yellow in yellow-green,

for example, the red and blue in purple whereas pure yellow like pure red, green or blue is a single unalloyed sensation. Nevertheless, a mixture of red and green *does* give yellow, a fact explained by the Young-Helmholtz theory. The antagonism of the single members of any of the color pairs postulated by this theory is emphasized by the fact that singles of any pair do not mix to give a composite color; e.g., a yellow-blue or a red-green sensation is unknown, whereas, the singles of *different* pairs combine to give various shades, e.g., orange, green-blue, yellow-green and purple. Of course, it is impossible to see, in terms of the theory, how a yellow-blue or a red-green sensation could be produced. It would mean that either of these sensations was caused by the simultaneous breakdown and synthesis of the same substance. But when we consider a sensation of gray this is precisely the conclusion to which the theory leads us. The theory also fails to account for the two well-known forms of color blindness (protanopia and deuteranopia, p. 979) and for McDougal's observation that red light seen by one eye and green light simultaneously by the other give a sensation of yellow. Fusion of the two sensations must be a cerebral process; in order therefore to explain the sensation of yellow there is no need to postulate the breakdown of a photochemical substance in the retina.⁶ As already mentioned, the Young-Helmholtz theory is supported by experiments in color matching, whereas Hering's theory is not.

The Ladd-Franklin theory attempts to overcome the objections that have been raised to the two foregoing theories and combines some of the features of both. It has been developed upon an evolutionary basis. Like Hering's it maintains the unitary nature of the sensation of yellow and is therefore a tetrachromatic theory; it is in agreement with the Young-Helmholtz view in that it postulates an initial tri-receptor photochemical mechanism, namely, the production of three elementary excitant substances by the action of red, green and blue light, respectively. It also conforms with the duplicity theory.

The colorless sensations—white, black and gray—are presumed to result from the action of light upon a substance (white substance) present in the rods (see fig. 418); it is the most elementary of the photochemical substances. Retinas possessing only rods and the most peripheral portions of the retina of man are therefore devoid of color sense. The cones are believed to be evolved from rods (Cajal) and accompanying this development the primitive white sensitive substance, through an intermolecular rearrangement, becomes responsive not only to white but to yellow (Y substance) or blue (B substance) light as well, yielding in each case

⁶ Goethe remarks, "We find from experience that yellow excites a warm and agreeable impression. . . . This impression of warmth may be experienced in a very lively manner if we look at a landscape through a yellow glass, especially on a grey winter's day."

⁶ An experiment of Abney is readily explained by the Young-Helmholtz hypothesis but not by Hering's. If one eye is fatigued by red (red elements being thus rendered relatively unresponsive) and then directed to a patch of pure yellow the latter appears greenish yellow.

a reaction product which sets up the nerve impulse. Visual evolution has reached such a stage in the retina of the honey bee, it being sensitive to white, yellow and blue light but not to red and green. This type of vision is also characteristic of the midzone of the human retina. The final change occurs in the yellow sensitive substance; acted upon by red or green light it gives rise to reaction products upon which the corresponding sensations depend. When the yellow and blue excitant substances are produced simultaneously they recombine to form the original substance from which they have been derived, and so to give rise to the sensation of white. Thus a blend of yellow-blue is impossible. Similarly the red and green substances if produced simultaneously combine to produce the sensation of yellow; if simultaneous production of the blue excitant occurs as well, the sensation of white results.

Though the theory has certain very attractive features, others of its postulates cannot be reconciled with observation. The most serious defect—a defect common to it and the theory of Hering—is its contradiction of Mueller's law (of specific nerve energies, p. 808).

FIG. 418. Illustrating Ladd-Franklin theory.

The theory seems to imply that the white substance gives rise, according to the type of stimulus, to any one of the four excitant substances within the compass of a single cone, which runs counter to the modern conception that the nerve fiber can carry only one type of message, i.e., that the character of the nerve impulse in whatever fiber it is transmitted is essentially the same.

Roaf's theory. This is a modification of the Young-Helmholtz trichromatic theory. Roaf concludes from the results of his determinations of the thresholds for color discrimination that there are three sets of color receptors: (a) those sensitive to long waves—from the red end of the spectrum to about $590\text{ m}\mu$, (b) those sensitive to medium and long waves, a spectral region extending from the red end to about $500\text{ m}\mu$ and (c) those sensitive to the whole of the visible spectrum. Red light stimulates all three sets; green stimulates *b* and *c*; blue stimulates only *c*. The sensation of white is due to the unequal stimulation of all three types of receptors in the order, $a < b < c$. It is suggested that the cones are the *a* and *b* receptors, and the rods the *c* receptors; the latter are the only ones stimulated by the short wave lengths and would therefore be those giving rise to a blue or violet sensation. This would account for the blue color of twilight vision—the so-called "blue sensa-

tion of the rods" of other observers, and for the blue appearance of a light of any wave length when it falls on the peripheral retina; it would also explain the impairment in the perception of blue in conditions associated with defective rod function e.g., night blindness and retinitis pigmentosa. The suggestion is made that the behavior, of the three sets of receptors may be due to the presence of colored oil globules acting as filters. Colored globules are found in the retinas of amphibians, reptiles and birds. The inner segments of the cones of the domestic hen, for example, contain well defined oil droplets, reddish in some cones, yellow green or colorless in others. Wald has isolated three carotenoid pigments from chicken cones which are closely comparable in their colors with those of the oil globules. The first could serve to transmit red light the second yellow and green and the third, light of all wave lengths. Oil globules have not, however, been demonstrated in the mammalian retina but in those animals in which they are found it is not improbable that they serve as filters for the differentiation of color.

THE DISTRIBUTION OF THE COLOR SENSE. The determination of the extent of the retinal areas sensitive to the three primary colors is important in many conditions, for changes in the distribution of the color sense may be one of the first changes to be detected in certain visual defects. When the normal retina is mapped out by means of the perimeter (p. 1007) it is found that the three primary sensations are distributed over four areas of different sizes which are centered, roughly, at a point a little to the inner side of the fovea. The largest area is for the perception of blue, a short distance within its circumference is the boundary of a smaller area for yellow. Next in size is the area for red; the area sensitive to green is the smallest; this last area is therefore trichromatic (sensitive to all three primary colors). A band surrounding it, i.e., the interval between the boundaries of the red and green areas is sensitive to blue, yellow and red, the third zone to yellow and blue, and the fourth to blue alone. The retina lying beyond the blue area as far forward as the ora serrata is achromatic, being sensitive only to white light, a colored object appearing gray or black. Minor variations in the extent and shape of the color fields are seen in different persons. The margins of the fields are rather irregular and include more of the nasal than of the temporal part of the retina, i.e., more of the temporal part of the visual field (p. 1007).

The different color zones have not a common boundary around the optic disc (blind spot) but show a concentric distribution the reverse of that

just described for the periphery. When color perception is investigated up to the margins of the disc the boundary for green is reached first, that for red next, then that for yellow and finally that for blue. A narrow zone beyond the latter and immediately surrounding the disc is sensitive only to white light.

COLOR BLINDNESS

We have seen that normal color vision is trichromatic, i.e., white light or any color can be matched by a mixture of three primary colors in suitable proportions. Color blindness is usually classified upon this basis into *anomalous trichromatic*, *dichromatic* and *monochromatic* types. The three forms could be explained in terms of the Young-Helmholtz theory by presuming that one or other color sensitive substance—red, green or blue—was defective or absent.

ANOMALOUS TRICHROMATIC VISION. In this defect, which was discovered by Lord Rayleigh in 1882, there is not complete blindness for any color, but the appreciation of red or of green is less than normal. The anomaly with respect to red is called *green-sightedness*, *partial protanopia* or *protanomaly*.

Subnormal perception of green is called *red-sightedness*, *partial deuteranopia* or *deuteranomaly*. The subject of partial protanopia in order to match a homogeneous yellow light with a mixture of red (λ 671 m μ) and green (λ 536 m μ) requires the addition of far more red than does a person with normal vision; the partial deuteranope requires more green. This is called the Rayleigh test. Anomalous trichromatic vision is looked upon as a transition stage between normal vision and the dichromatic form of color blindness.

DICHROMATIC VISION. There are three types of dichromatic vision, *protanopia* or *red-blindness*, *deuteranopia* or *green-blindness*⁷ and *tritanopia* or *blue-blindness*. For the sake of illustration we may presume that in this form one of the three photosensitive substances postulated by the Young-Helmholtz theory is lacking. Color vision is therefore a function of two variables instead of three, i.e., only two colors, green and blue in protanopes, red and blue in deuteranopes, or red and green in tritanopes, are required to match white or any color of the spectrum.

⁷ Many authorities, especially adherents of the trimeric hypothesis of color vision, refer to either protanopia or deuteranopia as red-green or green-red blindness, since in both conditions red and green are confused. Similarly, tritanopia is called yellow-blue blindness.

Protanopia is the commonest form; tritanopia is very rare. To the protanope the red end of the spectrum is shortened; red objects appear dark and may be confused with dark green, dark gray, dark blue or black. There is no darkening of the red end of the spectrum in deuteranopia. In protanopia the red-yellow part of the spectrum appears as different shades of green. John Dalton (1798), the famous English chemist, suffered from this type of color blindness and was the first to give a scientific account of it (1794); hence the term Daltonism. He says "Crimson has a very *grave* appearance, being the reverse of every showy and splendid colour. Woolen yarn dyed crimson or dark blue is the same to me . . . the colour of a florid complexion appears to me that of a dull opaque blackish-blue upon a white ground."

It has just been stated that in dichromatic vision, white or any spectral color can be matched by the mixture of two colors in suitable proportions. It follows therefore that in deuteranopes, a certain region of the spectrum (between λ 505 m μ and λ 492 m μ) appears colorless. This *neutral region* is blue-green to the normal eye. Wave lengths within this range therefore give the impression of a dirty white and when combined with other rays have a corresponding value in the mixture.

When mixed with other colors, red (in protanopes) and green (in deuteranopes) give sensations such as would result from equivalent quantities of gray or black. As a consequence of such anomalies, pale colors within the neutral range and certain shades of red and green or compound colors containing one or other of these, are confused (*confusion colors*). The dichromat matches pale green with grays, buffs and straw colors, as well as with pale green. The red-blind also confuses yellows with greens, a bluish pink (rose color) with pale blue or violet and dark reds with dark browns, greens or blues. Red-blind persons show, as a rule, a certain degree of red-green blindness as well.

The luminosity curve (p. 958) of the light adapted eye of dichromats differs from the normal, the maximum luminosity being nearer the blue end of the spectrum (about λ 585 m μ) in protanopes and nearer the red end (about λ 600 m μ) in deuteranopes (fig. 419). The luminosity curves of the dark adapted eye of dichromats and of normal persons are identical. Owing to the absence of color at the neutral point persons with dichromatic vision can detect smaller differences in luminosity than can those with normal vision. This serves the dichromat in discriminating between certain

colors which otherwise would be confused; actually, as a result of the improvement in this faculty, some 140 different hues can be differentiated by such persons—the number for the normal eye is only about 160.

About 4 per cent of males and 0.4 per cent of females⁸ show some degree of color blindness, the great majority of these being protanopes. Both forms of anomalous trichromatism and of dichromatism are nearly always hereditary. The condition follows a mode of inheritance similar to that of hemophilia, i.e., it is a sex-linked character carried in the X chromosome (p. 94 and p. 743). As mentioned on page 94 hemophilia may in very rare instances occur in a girl or woman should her father be a bleeder and her mother a transmitter. This also applies to color blindness which, owing to the more frequent occurrence of the condition as compared with hemophilia, accounts for the 0.4 per cent of females affected.

FIG. 419. Photopic luminosity curves of dichromats (protanopes and deuteranopes) compared with the normal trichromat. (After Abney.)

Tritanopia is nearly always acquired, i.e., due to some eye disease affecting the function of the rods, such as, detachment of the retina; yellows and blues are confused. The condition is simulated in jaundice because the blue rays are absorbed by the yellow bilirubin which stains the conjunctivae and ocular media. For a similar reason it is also seen as a temporary condition following the ingestion of a large dose of santonin.

Monochromatic vision or total color blindness is extremely rare. In a sense it may be looked upon as the converse of night blindness in that the function of the rods is unimpaired, but the color sensitivity of the cones is lost. To a person with monochromatic vision the surroundings appear as they do to one with normal vision at twilight, namely, in black, grays and white tinged with blue (blue sensation of the rods). The spectrum shows as in normal scotopic vision, maximal luminosity at about λ 535 $m\mu$.

⁸ Some authors (e.g., Waaler) gives figures as high as 8 per cent for males and 0.4 per cent for females.

TESTS FOR COLOR BLINDNESS. When one remembers the important part played by red and green—the two colors which are most commonly confused—in the control of our rapid transportation systems it is unnecessary to stress the dangers of defective color vision in operators, e.g., signal men, engine drivers, and seamen. In all civilized countries, applicants for employment in the marine and railway services must pass rigid color tests. Subjects of color blindness may be quite unaware of their defect, for they have no means of comparing their actual sensations with those of normal persons. They have learned to associate their own visual sensations with certain common names, e.g., red, green, etc., but unless their peculiarity is brought home to them by some glaring error, e.g., wearing a red tie to a funeral, they may not realize that the sensation which they know as red is not the same as that experienced by others. For this reason dichromats can usually name ordinary colors correctly and depend upon their power of fine discrimination between differences in luminosity to distinguish two colors which in hue appear to them alike.

Three types of test will be described.

(1) *Spectroscopic.* In this method the extent of spectral visibility,⁹ the discrimination between the different hues, the position and extent of the neutral band and the region of maximal luminosity are investigated. The determination and comparison of the ratio of red and green required to produce a homogeneous yellow (Rayleigh test) has been mentioned (p. 979). (2) *Matching.* One of the oldest and best of the methods is Holmgren's (1877) wool test. The examinee is given a set of colored wools among which are a number of so-called confusion colors. He is asked to select from the group those which match a separate wool of a specified color. In the first stage of the test the separate wool is a pale green. If he is red or green blind he matches it with cream, buff, dove gray, pale brown and straw-colored samples. He is next given a rose pink wool to match; if he chooses violet and blue wools he is red-blind, if greens, reds and browns he is green-blind. As a final test he is handed a red skein; the protanope chooses from the mixed wools dark greens and browns, the deuteranope pale greens and browns. (3) *Pseudo-isochromatic diagrams.* Ishihara's is the most satisfactory test of this type. The test comprises a series of cards upon each of which a colored field (pale green, rose, red, etc.) is printed in spots of different sizes. A

⁹ Roaf found in the investigation of twenty-four red-blind persons that the shortening of the red end of the spectrum varied considerably. In some, the red color extended to λ 620 $m\mu$, in others to λ 580 $m\mu$ and in a third group spectrum was colorless beyond only λ 480 $m\mu$.

letter or figure, also made up of spots, is outlined against the general field; these spots are of a color likely to be confused with that of the field. The subject is asked to name the figure or letter; it stands out clearly to the normal eye but to the color blind may be indistinguishable from the background.

FIG. 420. Illustrating contrast (Hering). Observe through tissue paper.

FIG. 421. Description in text.

FIG. 422. Color diagram showing complementary colors.

CONTRAST EFFECTS. It is well known that when black is placed against white or vice versa they "set one another off", the black looks blacker and the white a purer white than if either were placed against a colored ground. Gray also appears darker against a white than against a black ground (fig. 420). It is also true that blue against yellow ground (or yellow against a blue ground) more vivid than if placed against any other color. So, green is enhanced by red and red by green.

These phenomena are examples of *simultaneous contrast or spatial induction*.

The maximum effect of color contrast is obtained when *complementary colors* are placed side by side. Any pair of colors which when fused as lights produce white, are said to be complementary to one

FIG. 423. Optical illusion. The distance from A to B appears to be greater than that from B to C; they are the same.

FIG. 424. Illusion of size. The vertical lines are the same length.

FIG. 425. Zollner's lines. The long diagonal lines appear to converge; actually, they are parallel.

another.¹⁰ Examples of complementary color pairs are the following.

- Red and greenish blue
- Orange and cyan blue
- Yellow and indigo blue¹¹
- Violet and greenish yellow
- Purple and green

¹⁰ Two sheets of paper in complementary colors (e.g., red and bluish green) or two books with their covers similarly colored are laid flat in front of the observer as shown in fig. 421. A clear glass plate is held vertically above and midway between the colored surfaces. The far surface is seen directly through the glass and the near surface by reflection. A sensation of white is caused by the overlapping of the two images.

¹¹ A distinction must be drawn here between lights and paints; we know that yellow and blue paints when mixed give green, not white. The color of a paint is due to its reflecting certain wave lengths in white light and absorbing the remainder. Even the bluest paint is not pure blue; it absorbs all light but blue and a little green. These it reflects. A yellow paint is not pure yellow; it reflects a little green with the yellow. When the two paints are mixed, blue light is absorbed by the yellow paint, and yellow light by the blue. The green rays, of which a part is reflected by each separate paint are doubly reflected when the two paints are mixed.

Not only those listed above, but every color and shade of color has its complementary (fig. 422). There are consequently a great number of complementary pairs. When a color is placed in juxtaposition to gray, the gray appears tinted with the complementary of the color. For example, a lemon or other yellow object, placed in a bright light, casts a shadow which is tinged with blue—the complementary of yellow. The shadow cast by a red object becomes tinged with greenish blue, and one cast by a purple object with green. These principles are applied in art. The artist makes a yellow flood of sunshine more brilliant by painting blue into the shadows which in turn are given depth and an appearance of reality which otherwise they would lack.

When one stares for a time at a colored surface in a strong light and then directs the gaze to a gray surface it appears tinged with the complementary color, and objects of the complementary color itself are made more vivid. For example, if one looks at a red surface for a time and then at a green one the latter color is intensified. This phenomenon is called *successive contrast* or *temporal induction*.

AFTER IMAGES. If the gaze is directed to a bright white light for a moment and the eyes then closed or turned towards a dark surface, an image of the light slowly floats into view, becomes more distinct for a time and then gradually fades. Similarly, if the eyes are stimulated by a colored light or a brightly colored object of any sort, and then darkened, an image of the same color appears. These are called *positive after images*. If, instead of closing the eyes or turning them to a dark surface after looking at a white light, the retinas are stimulated a second time and diffusely by white, e.g., by directing the eyes to a sheet of paper, one then sees a dark image against a white ground. This is called a *negative after image*. If the first stimulus was colored, then the after image is in the complementary color. Negative after images of

colored objects are the cause of successive contrast described in the last paragraph. Either the Young-Helmholtz (p. 976) theory or Hering's (p. 977) can be fitted into the phenomena of negative after images.

The adherents of the former hypothesis propose that fatigue of one or other of the three types of cone is caused by the first stimulus. Cones which have responded to a given stimulus will not for a time respond again to one of the same type. White light stimulates all three types of cone. The negative after image which appears upon applying a circumscribed and then a diffuse white stimulus to the retina is, therefore, a dark patch against a white background. When the object looked at is colored and the retina is then stimulated by directing the eyes to a white surface, the image is in the complementary color because only those cones which had not been previously stimulated can respond. For example, if the object looked at is red, the red-sensitive cones are not excited by a subsequent stimulus of white; those sensitive to green and to violet alone respond, giving a sensation the complementary of red, namely, a bluish green.

According to Hering's view the first stimulus causes catabolism or anabolism of the particular substance (red-green, yellow-blue, etc.) concerned; the opposite reaction therefore occurs upon a second stimulus and proceeds until equilibrium becomes established.

Positive after images are apparently due to chemico-physical changes in the receptors of the retina caused by and outlasting the stimulus—a form of visual persistence.

OPTICAL ILLUSIONS. The brain may be deceived by imitations of certain effects upon which our visual judgments of the size, shape and distance of objects are based. Visual errors of this nature are called optical illusions or optical deceptions. Some interesting examples are shown in figs. from 423 to 425.

CHAPTER LXXVI

THE DIPOTRIC MECHANISMS OF THE EYE. CATARACT. OPTICAL DEFECTS. INTRA-OCULAR FLUIDS

PRINCIPLES OF REFLECTION AND REFRACTION. DEFINITIONS AND TERMINOLOGY

Light falling upon a surface undergoes *absorption* and *reflection*, and, if the material is transparent, the rays are transmitted through it, either with or without *refraction*.

The proportions of rays falling upon an opaque rough surface which undergo absorption and reflection, respectively, vary with the character of the surface. A large part of the rays striking a dull white surface, e.g., a sheet of paper, are reflected but, being thrown off at different angles to the perpendicular, they do not meet at a focus in front of, or, if continued backwards, behind the surface. The light reflected from such a surface is said to be *diffuse*.

The greater proportion of the light striking a polished surface (e.g. a mirror) is reflected, but *the incident and reflected rays are always in the same plane and the angles (angles of incidence and of reflection) which they make with the perpendicular are equal*. This statement is true for any polished surface whatever its shape (fig. 426).

Reflected rays from a plane mirror are divergent; if continued backwards they would meet at a point situated at the same distance behind the mirror as the object emitting the light lies in front of it. The eye placed in the path of the reflected rays projects them to this point, where a *full-sized erect image* is formed (fig. 427). Since the rays do not actually meet at this point but only appear to do so, the image is called *virtual*.

THE FORMATION OF IMAGES BY SPHERICAL MIRRORS. A spherical mirror is the segment of a sphere; its reflecting surface may be *concave* or *convex*; its *center of curvature* is the center of a sphere of which the reflecting surface forms a part. The middle point of the surface is called the *pole* of the mirror and a line passing through the pole and the center of curvature is termed the *principal axis*. The radius of the mirror is the distance from the pole to the center of curvature. Since the latter may lie on the same side as the source of light (concave mirror) or on the opposite side (convex mirror) the radius may be *positive* or *negative*, respectively.

Rays of light coming from a distant object, i.e., from infinity, are *parallel* (1 and 2, fig. 428), falling upon a *concave mirror* they are reflected as converging rays and meet in front of the mirror at a point (F) on the principal axis (p-o). This point (F) is the *principal focus* and the distance from it to the reflecting surface is the *focal length* or *focal distance* of the mirror. A *real*

inverted image of the object and *smaller* than it, is formed in the air at the principal focus. The rays from a near object are divergent; the reflected rays are therefore less strongly convergent than when the incident rays are parallel. If the object is at the

FIG. 426

FIG. 427

FIG. 428

FIG. 429

center of curvature (C) of the mirror then the rays are reflected back to this point and no image is formed. When the object is at *a* between the center of curvature of the mirror and the principal focus, its image is at A beyond the center of curvature; when the object is

beyond the center of curvature (at A) its image is between the latter and the principal focus, i.e., at *a*. These two points are therefore reciprocally related and are called *conjugate foci*. An object placed between the mirror and its principal focus emits rays which upon reflection are widely divergent and cannot be brought to a focus in front of the mirror. Projected backwards they meet a point behind the mirror where a *virtual erect* and greatly *enlarged* image is formed.

Parallel rays striking a *convex mirror* are reflected as *divergent* rays which to the eye appear to come from a point behind the mirror—the *principal focus* (F). Here a *virtual erect image*, smaller than the object, is formed (fig. 429).

REFRACTION. Rays of light in passing obliquely from one transparent medium to another of a different optical density (e.g., from air to glass) are bent or refracted. If one medium is surrounded by the other (e.g., glass in air) the ray is refracted twice. In passing from the medium of lower to the one of higher optical density the rays are bent towards the perpendicular;¹ in the transition from the denser to the rarer medium the bend is away from the perpendicular. With any two media the greater the obliquity of the incident rays the greater is the degree of refraction; rays perpendicular to the surface between the two media are not refracted. The ratio of the angle made by the incident ray (i.e., the ray falling upon the surface of the second medium) with the perpendicular (angle of incidence) to that made by the emergent ray (angle of refraction) is termed the *refractive index* or the *index of refraction* of the material in question. The refractive index is therefore a measure of refractive power. The refractive index of air being taken as unity, that of water is 1.3 and of ordinary glass 1.5.

Refraction by plane surfaces. Oblique rays striking a medium with plane parallel surfaces, such as a sheet of glass, are refracted to an equal degree upon entering and emerging through in opposite directions, i.e., towards and away from the perpendicular, respectively. The incident and emergent rays are therefore parallel though not quite in the same straight line (fig. 430). A *prism* has its sides inclined towards one another. Since a ray is refracted upon entering at one surface of the prism and again upon emerging at the other, and is bent nearer to the perpendicular in the former instance and away from the perpendicular in the latter, it will be refracted each time towards the base of the prism (fig. 431).

Lenses are of two main types, *spherical* whose surfaces are the segments of spheres and *cylindrical*. There are six varieties of the former—*planoconvex*, *biconvex*, *planoconcave*, *biconcave* and two *meniscus lenses*—*converging* and *diverging* (see fig. 432).

Convex lenses may be looked upon as a great number of truncated prisms with their bases directed towards the lens center. Concave lenses, on the other hand,

are as a number of prisms arranged with their base towards the periphery (fig. 433). It follows then that a symmetrical biconvex lens will bend rays to the same degree at equal distances from its center and bring

FIG. 430. The oblique ray (A) is refracted upon entering and leaving the block of glass. The emergent ray has the same direction as the entering ray but is not in the same line. P represents perpendicular. The ray B which strikes the glass surface perpendicularly is not refracted.

FIG. 431. ABC is a prism with the apex at A, the base BC, and the sides AB and AC. The angle of the prism is BAC. A ray of light DEFG is refracted at E and F as in figure 435. The total amount of refraction that is, the difference in direction between DE and FG, is represented by the angle DKH (the angle of deviation). If the eye is at G, the source of light, D, will appear to be at H. When the ray passing through the prism (EF) is parallel to the base (BC), the ray is said to traverse the prism symmetrically.

FIG. 432. Cross sections of lenses. *a*, planoconvex; *b*, biconvex; *c*, concavoconvex; *d*, planoconcave; *e*, biconcave; *f*, convexoconcave.

FIG. 433. See text.

them to a meeting point or focus, whereas concave lenses will cause divergence of the rays. In either instance the rays are bent towards the bases of the constituent prism.

¹ That is, they become more perpendicular.

Refraction by convex lenses. A line passing through the centers of curvature of the lens is termed the *principal axis of the lens*. Any other line intersecting the principal axis within the lens (i.e., a diagonal line) is called a *secondary axis*. The *radius of curvature* of the lens is the radius of a sphere of which the refracting surface forms a part. Rays passing through the principal axis are not refracted, for the incident and the emergent ray strike each surface perpendicularly and the two surfaces at these points are parallel (see above). Moreover, rays in the secondary axes undergo only very slight refraction and the incident and emergent rays, though not quite in a continuous line, are parallel, for again the surfaces which they pierce are parallel. The point where the principal axis is intersected by the secondary axes is termed the *optical center* or *nodal point* of the lens. In a biconvex lens with symmetrical surfaces the actual and the optical centers coincide, but in other biconvex lenses the nodal point may be situated nearer to one or other surface.

FIG. 434. See text.

FIG. 435. See text.

Light rays from a *distant object*, i.e., from infinity, are parallel (fig. 434). The point F where parallel rays meet after refraction is called the *principal focus*. The distance of this point from the lens is called the *focal length* or *focal distance of the lens*. The rays of a light placed at the principal focus traverse the same path but in the opposite direction, and emerge as parallel rays.

A *near object* emits divergent rays. If the source of light (fig. 435, B) is on the principal axis a little beyond the principal focus, an image is formed at a distance on the other side of the lens greater than its focal length (at C); when the object is placed in the second position (D) an image is formed at the first (B). These points are therefore, in respect to an object and its image, are interchangeable and are termed *conjugate foci*. If the object is situated at a distance exactly double the focal length of the lens the conjugate foci are at equal distances on the two sides of the lens. In all these instances a *true inverted image*, smaller than the object, is

formed. If the source of light (D) lies between the lens and its principal focus, the rays, after passing through the lens, are widely divergent. To the eye placed in the path of the emergent rays they appear to come from a point (V) at a greater distance behind the lens than the actual. A *virtual, erect and enlarged image* is formed.

Light rays in passing through a *biconcave lens* are diverged (fig. 436), therefore a *true image* is not formed. The eye in the path of the rays takes no account of refraction and the rays in consequence are projected backwards as straight lines which, meeting at a point

FIG. 436. See text.

FIG. 437. 1, refraction by a convex cylinder. A point of light is brought to a focus as a line after refraction through a cylinder. 2, refraction of light by a concave cylinder. Rays of light striking the cylinder perpendicularly to the axis A'A" are diverged, and appear to be brought to a virtual focal line F'F" (After Duke-Elder.)

on the other side of the lens, form a *virtual erect image*, smaller than the object.

Cylindrical lenses (fig. 437) have one plane surface, the other may be *convex* (*convex cylindrical lens*) or *concave* (*concave cylindrical lens*). A convex cylindrical lens may be regarded as a section of a cylinder sliced down its long axis; its horizontal meridian is convex. Rays transmitted through it at right angles to its vertical axis are converged as they would be by a convex spherical lens. Light traversing its long axis is not refracted, the lens acting in this axis as a plate with parallel sides. A lens of this type may be looked upon

as an infinite series of prisms arranged base to base in tiers. In the other type of cylindrical lens the horizontal meridian is concave; rays passing at right angles to the vertical axis are diverged.

THE REFRACTING MEDIA OF THE EYE. These are the cornea, the aqueous humor, the crystalline lens and the vitreous body. The refractive indices are given in the following table.

Cornea	1.34
Aqueous humor.....	1.33
Crystalline lens (whole).....	1.42
Vitreous body.....	1.33

It will be noticed that the refractive indices of the cornea and the aqueous humor are approximately the same; for practical purposes they may be taken as identical and the two be regarded as a single refracting medium. The eye, then, has three refracting surfaces, (a) the anterior surface of the cornea, (b) the anterior surface of the lens and (c) the posterior surface of the lens. The greatest refraction occurs at the corneal surface (42 diopters); of less importance is refraction at the surfaces of the lens (19 diopters with accommodation relaxed and 36 diopters in full accommodation). The value in the table above for the refractive index of the lens is calculated from the refractive power of the lens as a whole, as though it were a homogenous structure, but such is not the case. On the contrary, the lens consists of an almost spherical *nucleus* with a high refractivity (1.41) surrounded by a zone called the *cortex* of lower optical density (1.38). The surrounding cortex is composed of a series of concave meniscus lens, as shown in fig. 438. Thus an image formed by the anterior part of the cortex (B) is focussed by A and the second image in turn by C. The peculiar structure of the lens accounts for the apparent paradox that the mean value of the refractive indices of its parts (1.39) is less than the refracting power of the whole. Several important advantages are derived from this peculiar structure of the crystalline lens; it diminishes spherical and chromatic aberration (p. 1000), tends to prevent the scattering of light within the eye and enhances the power of the lens to alter its converging power during accommodation (p. 995).

The diopter. The converging or the diverging power of a lens depends upon the curvature of its surfaces (the greater the degree of curvature, the greater the refracting power) as well as upon the refractive index of the material of which it is composed. The focal length of a lens varies inversely with the refractive power and is therefore a convenient measurement for expressing

the strength of a lens. The standard focal length taken as 1 meter. The refracting power is expressed the reciprocal of the focal length, the unit being *diopter* (abbrev. D). Thus, the strength of a lens with a focal length of 1 meter is 1 diopter; of one with a focal length of 2 meters, $\frac{1}{2}$ a diopter; of one having a focal length of $\frac{1}{2}$ a meter, 2 diopters, and so on. The symbols + or - (+1 D, +2 D, -1 D, -2 D, etc.) are used respectively for a converging and a diverging lens. For example, if a concave lens has a refracting power -1 D, a small virtual image of a distant object will be focussed 1 meter from the lens and on the same side as the object. A convex lens of a corresponding power (+1 D) will bring parallel rays to a true focus 1 meter behind the lens. The power of a cylindrical lens is expressed in a similar fashion.

THE CONSTANTS OF THE EYE. Knowing the curvatures of the refractive surfaces of the eye and the distances between them as well as the refractive indices of the media, the path taken by the rays of light can be determined and the image co-

FIG. 438. Showing structure of the crystalline lens (diagrammatic).

structed. The values of the *constants of the eye* are given in the following table.

	mm.
Position of anterior surface of cornea.....	0
Position of posterior surface of cornea.....	0.6
Position of anterior surface of lens.....	3.6
Position of posterior surface of lens.....	7.2
Position of retina.....	24.1
Radius of anterior surface of cornea.....	7.7
Radius of posterior surface of cornea.....	6.8
Radius of anterior surface of lens.....	10.0
Radius of posterior surface of lens.....	6.0

The refractive indices of the media have been given above.

Construction of the image from the foregoing data is a very laborious proceeding. To start with, the image formed by the first refracting surface is constructed; this image now serves as the object for the next refracting surface, the second image in turn is the object of the third surface and so on. The matter is very much simplified, however, by constructing the *diagrammatic* or *schematic* eye by the application of the theorem of Gauss. This states that every optical system composed of spherical surfaces with their centers

on the principal axis has three pairs of cardinal points. These are, two *principal points* (K and H', fig. 439), an *anterior* and a *posterior focal point* (ϕ and ϕ') and two *nodal points* (K and K').

The *first and second principal points* lie close together in the anterior chamber 2 mm. behind the cornea. Planes passing through the principal points and perpendicular to the axis are termed the *first and second principal planes*; an object in the first principal plane forms an erect *full-sized image* in the second and vice versa. The first and second principal points correspond, therefore, to the conjugate foci of a single lens.

The anterior focal point (ϕ) is situated 15.7 mm. in front of the cornea. Rays from this point in the axis would, after passing through the system, emerge as parallel rays. Parallel rays entering the system are focussed at ϕ' which is situated on the retina. ϕ and ϕ' therefore correspond to the principal foci of a single lens (p. 985).

This has a single ideally refracting surface situated in the anterior chamber 1.35 mm. behind the cornea and with a radius of 5.7 mm. The nodal point or optical center of the reduced eye lies 7.08 mm. the principal point 2.3 mm. and the posterior focal point 24.13 mm. behind the anterior corneal surface. The anterior focal point is 15.7 mm. in front of the cornea. The distance of the nodal point from the retina, i.e., the focal length of the eye, is $(24.13 - 7.08 =) 17.05$ mm. The refracting power is therefore $\left(\frac{1000}{17.05} =\right) 58.65$ diopters.

By means of an X-ray beam, which is not refracted, projected into the eye Goldman and Hagen have measured the length of the globe in the living human subject. The value obtained (23.4 mm.) agrees closely with that of the schematic eye. The value for the total refractive power of the normal human eye, as determined by these observers, is also in close agreement, namely, 59.22 diopters.

FIG. 439. The cardinal points of the eye. ϕ , The anterior focus, 15.7 mm. in front of the cornea. ϕ' , The posterior principal focus, 24.13 mm. behind the cornea—that is, upon the retina. H, H', the principal points, in the anterior chamber. KK', the nodal points, in the posterior part of the lens. (After Duke-Elder.)

The nodal points (K and K') also lie close together on the axis and near the posterior surface of the lens. They correspond to the optical center of a single lens. Rays passing through the nodal points are not refracted. A ray entering the system and passing through K appears to come from K' and emerges along a line parallel to that along which it entered. The following table for the schematic eye gives the distances of the six cardinal points from the anterior surface of the cornea.

	mm.
Anterior surface of cornea.....	0
First principal point, H.....	1.7
Second principal point, H'.....	2.0
First nodal point, K.....	7.0
Second nodal point, K'.....	7.3
Posterior focal point, ϕ	24.1
Anterior focal point, ϕ'	15.7

The two nodal points lie so close together that no significant error is entailed if they are taken as one; the same may be said for the principal points. Thus the compound optical system of the eye can be simplified to the so-called *reduced schematic eye* of Listing.

THE FORMATION OF THE IMAGE ON THE RETINA. Knowing the foregoing measurements, the paths taken by the light rays can be drawn and a construction of the image upon the retina readily carried out. The formation of the retinal image is illustrated in fig. 440. The large arrow A-B represents an object emitting divergent rays which are converted and brought to a focus to form the image represented by the small arrow a-b. The retinal image, it will be observed, is smaller than the object and inverted. For the sake of simplicity only four rays are shown, two from a point at either end of the object, but of course the surface of an object consists of an infinite number of points, each of which emits divergent rays. One of each pair of rays in the figure (solid line) passes unrefracted through a secondary axis (i.e., through the nodal point N), the ray from the upper part of the object to the lower part of the retina and vice versa. The other ray of each pair (dotted line) undergoes refraction and meets the corresponding

unrefracted ray. Similarly, rays from a point on one side of the object will fall upon the retina as a point of light in the opposite part of the image. Thus, it is seen how the image on the retina becomes inverted. Of course we see objects in their true position. Re-inversion is a cerebral function developed, probably, through the association of visual sensations with those of touch. The process itself is essentially psychological and beyond our ability to analyze.

The idea that the retinal image is inverted was at first difficult to believe. Kepler (1604) inferred from his optical studies that this must be so, but it was Scheiner (1625) who furnished the proof by observing the back of an excised eye from which the sclerotic and choroid coats had been removed. The inverted image of an object was clearly visible upon the translucent retina. The inversion of the retinal image may also be demonstrated during life in persons of blonde complexion because their choroid contains little pigment.

FIG. 440. Illustrating the formation of the retinal image.

The subject is examined in a darkened room, the eye being turned towards a lighted candle placed well to the temporal side. An inverted image of the flame may be seen showing through the inner side of the wall of the globe. The retinal image can be seen most readily by means of the ophthalmoscope or in the excised eye of a rabbit whose choroid is devoid of pigment.

The size of the retinal image is dependent upon the angle $a N b$, (fig. 440) this—the angle subtended at the nodal point of the eye by an object in the visual field—is called the *visual angle*. The size of the image can be calculated if one knows the distance of the nodal point of the eye from the object and from the retina, and the size of the object. Thus in the figure $A B$ is the object and $a b$ its image. The triangle $A N B$ and $a N b$ being symmetrical, then

$$a b : A B = b N : B N$$

$$a b = A B \times \frac{b N}{B N}$$

$$b N = 17.05 \text{ mm.}$$

$$i = 17.05 \times O/d$$

i is the size of the image, O the size of the object and its distance from the nodal point of the eye (17.05 = distance of retina from nodal point, see p. 987).

THE OPHTHALMOSCOPIC EXAMINATION OF THE EYE. Under ordinary circumstances we cannot see within the eye of another person, because only a limited quantity of light enters his eye through the relatively small pupillary aperture. It is like trying to look through a small window into a darkened room. Furthermore, the pupil constricts and, of the light which passes through the pupil a large part is absorbed by the pigment layer of the retina.² Even when a light is brought close to the eye under observation, one is unable to see the retina, because the pencil of parallel rays which emerge do not enter the examiner's pupil unless his eye is directly in its path, and when he attempts to bring his eye into the proper position either his head comes between the light and the subject's eye or the light (if between himself and the subject) dazzles his sight.

These difficulties are overcome by means of the ophthalmoscope. This instrument consists of a small mirror with a central perforation through which the observer views the subject's eye. Light furnished by an electric lamp placed above the head of the patient is reflected from the mirror and the pencil of rays emerging from the subject's eye passes through the aperture of the mirror to the examiner's eye (fig. 441).

The invention of the ophthalmoscope is commonly attributed to Helmholtz (1851) but a crude device based upon the same principle was used by Babbage two years previously. The instrument consists of two mirrors, each with a central aperture. One mirror is plane, the other concave; they are pivoted so that one or other can be rotated into position as required. The obverse side of the instrument holds a series of small lenses ranging from + 30 D to - 30 D in strength, any one of which can be moved into position over the central aperture. The examiner seats himself 1 meter from the subject and looking through the peephole of the plane mirror reflects a beam of light into the eye. If the observed eye is emmetropic a uniform red glow—the *red reflex of the fundus*—caused by reflection from the retina is seen lighting up the pupil. No detail.

² The red glow seen in the eyes of certain animals, especially of the cat and other carnivora, is due to the presence of a highly polished area at the fundus—the *tapetum lucidum*—which acts as a concave mirror to throw back a large proportion of the light which enters the eye. This structure lies behind the retina, the pigment layer being absent over it. It is composed of several layers of flattened endothelial cells overlain with doubly refracting crystals.

e.g., optic disc or retinal vessels, is visible because the rays emerging from the subject's eye are in two parallel beams which soon diverge and cannot be brought to a focus upon the observer's retina. On the other hand, if the eye is hypermetropic or myopic an image is formed. In the former state the emergent rays are divergent and appear to meet behind the eye where a virtual, erect image of the retina is formed. In myopia the emergent rays are convergent and, meeting in front of the eye, form a true inverted image.

After this preliminary examination one or other of two methods of ophthalmoscopy—the indirect or the direct—may be employed. In both methods the concave mirror is used. In the *indirect method* a separate biconvex lens with a focal length of 7.5 cm. (about 13 D) is held in front of the eye of the examinee. The observer seats himself 1 meter away and holds the lens in the path of the beam from the mirror and a short distance in front of the eye under observation. The pencil of parallel rays emerging from the subject's eye will be brought to a focus by the biconvex lens; a highly magnified, real and inverted image is formed in

FIG. 441. Illustrating the principles of the ophthalmoscope. E, light; L, lens; M, mirror; O, observer; S, subject.

the air at the principal focus of the lens, i.e., between it and the examiner. The subject turns his eye a little inwards in order to bring the optic disc into view, being directed, for example, to look at the observer's left ear if his left eye is being examined. By moving the lens towards or away from the subject's eye a point is reached where his retina is brought into focus and the optic disc with its vessels (Plate II) clearly seen. In the *normal* eye the image is formed as follows. The diverging rays from the light are reflected from the concave mirror along converging lines. The rays are converged further in passing through the biconvex lens and the refracting media of the eye and are brought to a focus on the patient's retina (fig. 441). Upon reflection from the fundus they emerge from the eye along parallel lines; they are next converged by the biconvex lens and, as mentioned before, form a large inverted image in the air (see fig. 442 A). In the *hypermetropic* eye the emergent rays are divergent. They appear therefore to come from a point behind the eye where a large, erect virtual image is formed. The lens, using this as object forms a small inverted image of it at a greater distance in front of the lens than its focal

length (fig. 442 B). In myopia the emergent rays are convergent and will form an inverted image of the retina at $\alpha\beta$ (fig. 442 C). The biconvex lens forms of this a final small image $a b$ within its own focal length.

In the *direct method* a field of smaller area but of higher magnification is seen. The light is placed behind the patient's head and to one or other side, depending upon the eye to be examined. The examiner comes quite close to the subject and without the aid of a biconvex lens observes the fundus (right fundus with his own right eye, and left fundus with his left eye). The small concave mirror, which is set obliquely in the in-

FIG. 442. A, path of the light from the eye in the indirect method of ophthalmoscopy in emmetropia. AB , the illuminated area on the retina, gives an image, ab , in the air on the side of the condensing lens farthest from the eye. B, path of the rays of light from the eye in indirect ophthalmoscopy in hypermetropia. AB , the illuminated area on the retina gives an imaginary image $\alpha\beta$ behind the eye. This is focused in a final image at ab by the condensing lens. C, path of the rays of light from the eye in indirect ophthalmoscopy in the myopic eye. AB , the illuminated area on the retina, forms an inverted aerial image in front of the eye at $\alpha\beta$. The condensing lens gives a final image (ab) situated within its own focal length. (After Duke-Elder, *Text Book of Ophthalmology*.)

strument, is rotated to the proper angle to throw a reflected beam through the pupil. The light, after coming to a focus on the retina, emerges from the emmetropic eye as parallel rays which are brought to a focus upon the observer's retina. If, however, the subject's eye is hypermetropic (p. 1001) the emergent rays will be divergent and can only be focussed by the examiner if he accommodates his eye or interposes a convex lens; if the observed eye is myopic the reflected rays are convergent; the examiner must then use a concave lens in the order to focus the image upon his own retina.

Papilledema (choked disc, optic neuritis) and optic atrophy. In conditions accompanied by high intracranial pressure, e.g., brain tumor, hydrocephalus and uremia, the optic disc loses its natural translucency and becomes reddened and swollen. The central vein is engorged and tortuous and the venules and capillaries dilated. Small hemorrhages may be seen. The swelling of the disc is due to the transudation of fluid from the engorged vessels and its collection in the anterior layers of the lamina cribrosa and between the nerve fibers. The physiological cup becomes gradually filled up, and may eventually be elevated above the general level of the surrounding retina. The circumference of the disc ill-defined, appearing blurred or "woolly." The disc is enlarged and its lateral spread causes the retina to be thrown into folds or ridges. In the older terminology these changes were referred to as choked disc, optic neuritis or papillitis. The condition is now called *papilledema*. The separation and stretching of the nerve fibers, their compression where they penetrate the lamina cribrosa and the overgrowth of glial tissue set up by the presence of the edema fluid leads to nerve atrophy—*secondary optic atrophy*. The disc in this

FIG. 443. Description in text.

condition is a grayish or dead white, due to the obliteration of capillary vessels by the overgrowth of glial tissue. The optic cup is deepened as a result of the degenerated nerve fibers. The outline of the pale disc is clearly defined against the surrounding retina. The retinal veins are engorged but the arteries are narrower than normal.

It is now almost universally agreed that mechanical factors alone are concerned in the production of papilledema. The optic nerve, it will be recalled, is invested by prolongations of the cerebral meninges—the *pia*, *arachnoid* and *dura*. The spaces between these three layers of the nerve sheath—the *subarachnoid* and *subdural spaces*—are continuous, as was first shown by Schwalbe (1870) with the corresponding spaces within the cranium. The *dura* and *arachnoid* of the nerve sheath, however, are in close opposition, there being only a potential subdural space in this situation. But the intracranial subarachnoid space is in free communication with the corresponding space of the nerve sheath and the intracranial pressure is transmitted through the cerebrospinal fluid to the intravaginal space right up to the lamina cribrosa. The central vein of the

retina with its companion artery makes an almost right angled bend as it leaves the optic nerve and, crossing the intravaginal space, pierces the arachnoid and dissects a short distance behind the eyeball (fig. 443). A marked rise in intracranial pressure distends the sheath for the *dura* in this situation differs from that within the cranium in being unsupported by bone (Macdonald). The elevated pressure thus transmitted to the sheath tends to compress the vein in its course across the intravaginal space and to impede the venous return as well as to block the lymph channels situated in the adventitia of the central vessels. Little or no interference is offered to the blood flow in the artery owing to its more resistant wall and to the higher arterial blood pressure. The venous pressure rises and the intraocular part of the vein and its branches become engorged since they are beyond the influence of the intracranial pressure.

Papilledema is therefore comparable with an edema which may occur in almost any situation as a result of obstruction of the venous and lymphatic channels while the arteries remain pervious. No evidence that papilledema is inflammatory in nature can be found upon histological examination (Holmes and Paton). The theory that high intracranial pressure causes edema of the disc by raising the pressure in the cavernous sinus (which receives blood from the central vein either directly or through the superior ophthalmic vein) is controverted by the following facts. (a) The central vein of the retina after piercing the *dura* anastomoses with the orbit with one or other of the ophthalmic veins (usually the superior) and through it with the pterygoid venous plexus and the facial vein. Thus an alternative system of channels is provided for the drainage of blood from the retina. (b) Ophthalmic changes are not seen as a rule in thrombosis of the cavernous sinus.

It has been suggested by Macdonald that cases of retinal detachment which sometimes follow a powerful straining effort (e.g., lifting a heavy weight) may be due to an acute retinal edema caused by the sharp rise in intracranial pressure which such acts induce. In this view the distension of the nerve sheath by cerebrospinal fluid causes the central vein to be bent more acutely at the point where it leaves the nerve and that the venous congestion is caused in this way rather than by pressure upon the vessel in its subarachnoid course.

Atrophic changes in the disc occurring unpreceded by papilledema are referred to as *primary optic atrophy*. The main causes of primary optic atrophy are pressure upon the nerve within the cranium as by a tumor, certain nervous diseases (tabes, general paralysis of the insane and disseminated sclerosis) and toxic substances, e.g., wood alcohol, quinine, lead and salicylic compounds. Since the optic nerve fibers have their cell bodies in the retina (ganglion cell layer) the atrophy of the section between the point of pressure and the retina is in the nature of a retrograde degeneration (p. 779). As already mentioned on page 779, the optic nerve is devoid of a neurilemma; regeneration

therefore never occurs. In tabes and general paralysis of the insane the atrophy is probably the result of a syphilitic meningitis which affects the nerve secondarily. The toxic substances mentioned exert their action apparently directly upon the ganglion cells of the retina.

RETINOSCOPY OF SKIASCOPY. This is a reliable objective method for determining the refraction of the eye. It is of special value in children and others for whom the reading of test type is impracticable, and for the detection of malingerers. The test, which will now be described, was first employed by Cuignet (1873). When a lighted candle is placed in front of the eye the rays are brought to a focus or a partial focus upon the retina. Since the retinal image is inverted, a movement of the candle to one side causes the illuminated area on the retina to move in the opposite direction. Rays from the candle or other luminous object reflected from a plane mirror form a virtual image behind the reflecting surface (p. 983). Tilting the mirror to one or the other side causes this image to move in the opposite direction. Consequently, when the reflected light is thrown into the eye by means of a plane mirror, owing to a double reversal of the movement taking place (i.e., a movement of the mirror image which now serves as the luminous object in one direction and of the retinal

FIG. 444. Retinoscopy shadow. (After Duke-Elder.)

image in the other), a change in the inclination of the mirror causes the illuminated area upon the retina to move in the *same* direction as the tilt. This movement of the illuminated area on the retina in relation to the tilt of the mirror is the same whatever the refractive state of the eye. But the rays from the illuminated area on the retina are reflected back through the pupil and undergo refraction; the appearance of the image of the light to the eye of the observer depends upon the direction of the emergent rays.

If the eye is *emmetropic* or *hypermetropic*, or *myopic* to a degree less than $-1D^3$ the image is seen by the observer as a bright area bounded by a faint shadow with a vertical (straight) border (fig. 444). In degrees of myopia greater than $-1D$ the shadow is deeper, more clearly defined and has a concave edge. In myopia of $-1D$ no shadow is seen, the pupil is either uniformly illuminated or entirely dark. As the mirror is tilted the direction, rate and excursion of movement of the shadow varies according to the refractive state of the eye. In emmetropia, hypermetropia and degrees of myopia less than $-1D$ the image moves *with* (i.e., in the same direction as) the tilt of the mirror. In

degrees of myopia greater than $-1D$ the image moves *against* the mirror (fig. 54 A). With a myopia of $-1D$ the two opposite movements are neutralized and, as mentioned above, no definite line of shadow can be observed. At this point—the so-called *point of reversal*—a weak concave or convex lens placed in front of the subject's eye causes the shadow to reappear and to move, respectively, *with* or *against* the tilt of the mirror. These facts are explained as follows. In myopia the emergent rays are convergent and form an inverted image in the air at the far point of the eye (p. 1000). Since, as mentioned above, the illuminated area on the retina in all instances moves with the mirror the inverted image must move against it when the myopia is greater than $-1D$ and the observer is placed a little more than 1 meter distant, i.e., the image is formed

FIG. 445. Illustrating the movements of the shadow in retinoscopy. A, in *myopia*. When the mirror is in the position AB, the image is at D in the highly myopic eye, and at C in the less myopic eye. When the mirror is in the position A'B', the respective images are in the positions *d* and *c*. Since *Dd* is less than *Cc*, the lower the degree of myopia, the larger the excursion and the quicker the movement of the shadow. B, in *hypermetropia*. When the mirror is in the position AB, the image is at D, in the highly hypermetropic eye and at C in the less hypermetropic eye. When the mirror is in the position A'B' the respective images are at *d* and *c*. (After Duke-Elder, *The Practice of Refraction*.)

between the subject and the observer. It will be clear from fig. 445 that the higher the degree of myopia, i.e., the closer the far point of the subject, the slower will be the movement and the smaller its excursion. In myopia less than $-1D$ the emergent rays meet and form an image at a distance greater than 1 meter, i.e., the observer's eye is situated closer to the subject's eye than its anterior focal distance. The shadow therefore moves *with* the mirror.

In hypermetropia the emergent rays diverge and appear to come from a point behind the subject's eye; here an apparent erect image is formed. The shadow, therefore, as shown in figure 445 B, moves with the mirror, its speed being slower and its excursion smaller the greater the refractive error. The point of reversal occurs when the far point of the subject and the ob-

³That is, $-1D$ would be required to correct the error.

server's eye coincide. Therefore, at the usual distance at which the examiner is seated, this occurs when the myopia amounts to -1 D. The far point of the emmetropic eye is at infinity, therefore reversal in such an eye occurs should the observer place himself at a distance of 20 feet or more from the subject, i.e., at infinity.

The presence and the degree of a refractive error is determined in the following manner. The observer is seated at a distance of 1 meter from the eye to be observed. Light from a source above the subject's head is reflected into his eye by means of a plane mirror with a central aperture, and the appearance and movements of the shadow noted. If the pupil is uniformly illuminated or black but no definite shadow is discernible, the eye has a myopia of -1 D. Should a shadow be present and it moves *with* the mirror the eye is either emmetropic, myopic to a degree less than -1 D or hypermetropic. Convex lenses are then added until the shadow disappears (point of reversal): a slightly stronger lens ($+0.25$ D) is then added, which should cause a movement opposite in direction to that originally present, i.e., the error is slightly overcorrected. If, on the other hand, the shadow moves originally *against* the mirror, the eye has a myopia greater than -1 D; the same procedure as that just described is followed, using concave lenses. Since the point of reversal indicates a myopia of -1 D, 1 diopter must be subtracted in each instance in order to obtain the actual value of the refractive error. In other words, a lens of $+1$ D makes the eye more myopic by -1 D than it actually is. If the total value of the lenses added is only $+1$ D the eye is obviously emmetropic.

BIOMICROSCOPY—THE SLIT LAMP. By means of this instrument an intense narrow beam of light is thrown obliquely into the eye and a small section of the cornea, anterior chamber, iris, lens or anterior part of the vitreous observed stereoscopically through a binocular microscope. The beam passes through an adjustable slit which when narrowed to minimum width concentrates the beam of light upon an area as small as 0.05 mm. in diameter. The illuminated section is in the form of a prism, or more correctly of a parallelepiped. The tissues within this section are magnified some 25 diameters. Under this method of examination ocular structures which ordinarily appear homogeneous show a definite pattern, and any abnormality is readily recognized by one familiar with the appearance in health. For example, the anterior and posterior epithelial layers of the cornea are seen as bright lines bounding the less luminous substantia propria, and any pathological condition, e.g., erosions, small opacities, keratitis, etc., are easily detected. The laminated structure of the lens is clearly revealed. The central nucleus and the cortical layers are marked by luminous boundaries; the lens sutures appear as darker lines.

ENTOPTIC PHENOMENA. Visual sensations may arise from images of objects situated within the eye itself. The most familiar of these are the

muscae volitantes (L. *flying flies*) which are seen as faint specks projected a short distance in front of the eye. They are due to shadows cast upon the retina by small semi-opaque particles in the vitreous body, such as epithelial cells, small coagula or embryonic rudiments. Particles lying close to the retina are most likely to give rise to the sensations. Lying behind the axis of rotation of the globe such particles cast shadows which move downwards over the retina when the eye is turned upwards but, since the direction of any movement on the retina is reversed in consciousness, they appear to move upwards. This upward movement is followed by a slower downward movement. When any attempt is made to fix one's sight upon the specks they dart away, from which fact the name was probably derived. The movements of shadows caused by particles in the anterior chamber or in any part of the eye in front of its axis of rotation would, of course, be in the reverse direction.

Ordinarily the retinal vessels which, it will be recalled, lie outside the fovea and superficial to the retinal layers, are not perceived. One probable reason for this is that we have come through habit to ignore them, but other factors of a more physiological or anatomical nature have been suggested. Helmholtz, for example, thought that the sensitivity of the retina underlying the vessels was greater than elsewhere, so that the light reaching the retina through them, though reduced in intensity, caused as great an effect as light falling in unshielded regions. At any rate, when light is thrown into the eye at such an angle (e.g., obliquely through the sclerotic) that the shadows of the vessels fall upon a retinal region unaccustomed to receive them, they become visible. If, while his eye is being illuminated in this way in a dark room, the subject looks towards a screen he sees a highly magnified image projected against the uniform surface. The vessels appear as an intricate branching pattern against a bright ground and are known after their discoverer, as *Purkinje figures*. A method which anyone can employ by himself to make the extrafoveal capillaries visible is to look at a bright surface through a pin-hole in a card held close to the eye while he oscillates the opening quickly from side to side and thereby shifts the shadows from point to point in the retina. The capillaries may also be observed by looking through a microscope from which the objective (but not the eyepiece) has been removed and moving the head rapidly from side to side.

Mueller (1855) made use of Purkinje's observation (1811) to prove that the light sensitive elements are the rods and cones. Moving the source of light causes the images to change their positions on the screen. If we measure the distance of this shift (fig. 446, A-B) and the distance between the two positions of the light (a-b) then, knowing the distance of the nodal point of the schematic eye (N) from the retina and from the screen, the position of the shadow (α - β) relative to the vessels (v), i.e., the distance α v, can be calculated. This was found to be from 0.17 to 0.36 mm., which is by actual measurement the approximate distance of the vessels in front of the rod and cone layer.

The corpuscles moving in the retinal capillaries can be observed if the eye is directed to a uniformly illuminated surface. The best way to perform this experiment is to look at the sky through a dense blue-violet glass plate. The blood cells then appear projected upon the plate. It is actually possible to calculate the speed of the corpuscles from the distance between their positions at the beginning and end of a given time interval. Vierordt (1873) was the first to make such an estimation. Knowing the distance of the nodal point of the eye from the retina and from the glass screen, the magni-

FIG. 446. Description in text.

fication of the travelled distance can be determined (p. 988).

Other entoptic phenomena which should be briefly mentioned are the colored halos seen around bright lights, especially in dark surroundings. The halos consist of a series of concentric rings of rainbow colors—from blue to red from within out. Actually they are diffraction spectra, due to the structures of the eye acting as diffraction gratings. There are two kinds of halo—*lenticular* and *corneal*. The first is attributed to the radial fibers of the lens and is the larger. The corneal type is believed to be due to the epithelial and endothelial cell layers of the cornea.

THE ACCOMMODATION OF THE EYE

ANATOMICAL SKETCH

Before giving an account of the physiological mechanism of accommodation, the structures concerned, e.g., the ciliary body and the crystalline lens will be briefly described.

THE CILIARY BODY. When the interior of the anterior half of the eyeball is exposed by a transection through its equator, a transparent disc—the *crystalline*

lens—is seen occupying the center of the bowl-shaped structure (fig. 447). On the wall of the globe some distance behind the circumference of the lens lies the dendate border of the retina proper known as the *ora serrata* (p. 956). The ciliary body is a circular zone of tissue extending forwards from the ora serrata to a short distance from the circumference of the lens. It is covered on its inner aspect by the pigment layer of the retina, which we have seen is continued forwards (as the *pars ciliaris retinae*) from the point of termination of the neural layers. The ciliary body consists of three parts, the orbiculus ciliaris, the ciliary processes and the ciliary muscle. The *orbiculus ciliaris* immediately adjoins the choroid, of which it may be considered the direct continuation. It is a band about 4 mm. broad encircling the eyeball and presents on its inner aspect a number of radially arranged ridges. The *ciliary processes* appear as some seventy triangular elevations on the inner aspect of the ciliary body; they project towards the axis of the eye and form a series (*corona ciliaris*) of radial fringes which completely

FIG. 447. Showing interior of anterior half of the eyeball.

encircle the equator of the lens, but are separated from it by a very short interval. The great bulk of the ciliary body is composed of the ciliary processes and the ciliary muscle. The fibers of the *ciliary muscle* are arranged in two sets, an outer *meridional* and an inner *circular*. The meridional fibers arise from the scleral spur (p. 1004); radiating backwards and laterally they are attached to the ciliary processes and to the orbiculus, and through the latter to the choroid. The circular fibers are fewer; in meridional sections of the globe they appear as a small bundle of cross-sectioned fibers lying behind the angle of the iris (fig. 448). As a matter of fact, these fibers are not uniformly circular in direction but take different courses and, interlacing with one another, form a reticulated ring-shaped band (fig. 449). Taken as a whole this part of the ciliary muscle constitutes a sphincter (*sphincter muscle of Mueller*) situated in front and to the outer side of the ciliary processes. The fibers composing the margin of the central opening are mainly circular and are attached to a band of elastic tissue situated at the angle of the

iris; the outer circumference of the sphincter is connected to elastic fibers which are continuous with similar fibers of the choroid. The muscle is thus anchored by two elastic attachments.

THE CRYSTALLINE LENS is a transparent, biconvex, circular structure about 11 mm. in diameter and between 3.6 and 3.9 mm. thick at the center. It is situated with the center of its anterior surface coinciding with the center of the pupil; the pupillary margin lies in contact with this surface. The center of the anterior surface is termed the *anterior pole* of the lens, the center of its posterior surface, the *posterior pole*. An imaginary line joining the poles is called the *principal axis*. The two surfaces meet at the circumference in a rounded edge termed the *equator*. The posterior surface in the young adult is decidedly more convex than the anterior

FIG. 448. Showing structures in the region of the angle of the iris.

FIG. 449. Showing arrangement of circular fibers of the ciliary muscle. (After Fincham.)

(see table, p. 986); this difference diminishes somewhat with age. The lens is enclosed in a structureless, highly elastic capsule. The latter is not of uniform thickness, being thinner over the posterior than over the anterior surface, and the part covering the central region of each surface is thinner than the corresponding peripheral parts. The values in ascending order of thicknesses are, center of posterior surface (av. 2.2μ), peripheral part of posterior surface (av. 13.7μ), center of anterior surface (av. 15.7μ), peripheral part of anterior surface (av. 18.2μ) (see fig. 450). A single layer of columnar epithelial cells covers the anterior surface of the lens immediately beneath the homogeneous capsule; the latter is formed as a secretion of these cells. The substance of the lens consists of a series of ribbon-like fibers which arise from the region of the equator and

are actually greatly elongated epithelial cells (fig. 451). By careful examination of the lens, from the most central part of the anterior surface to the region near the equator the gradual transition of the columnar cells into the attenuated cells of the lens substance can be traced. The fibers proceed from the equator toward the lens center and, abutting against fibers coming from other segments of the periphery, fuse along well-defined lines—the *lens sutures*. These are seen in the adult lens as a series of faint irregular striae radiating from the center to form what is known as the *lens star*. On section, the lens shows a series of concentric lamellae with a nucleus of extreme convexity and high refractive index, and a less refractive cortex. The optical advantages of this construction have been pointed out (p. 986). The nucleus is also of much firmer consistency than the cortex which is relatively soft and pliable.

The interval between the ciliary processes and the equator of the lens is occupied by a circular membrane

FIG. 450. Showing the regional variations in thickness of the lens capsule. (After Fincham.)

FIG. 451. Meridional section of the lens. (From Wolff after Poirier and Becker.)

band; this is the anterior part of the *zonula ciliaris* (*zonula of Zinn*). The precise origin of the fibers of the zonula is disputed, but they appear to arise as a system of transparent fibers from the anterior part of the hyaloid membrane (p. 1002) 1.5 mm. or so in front of the ora serrata. Passing forwards they form a series of bundles which occupy grooves between the ciliary processes, and then bridge the gap, as just mentioned, between the ciliary processes and the lens. Near the lens circumference the zonula splits into an anterior and a posterior lamina; the former is the thicker of the two and blends with the lens capsule a little in front of the equator, constituting what is generally known as the *suspensory ligament* of the lens. The space between the two layers of the zonula is called the *canal of Petit*. Slits in the layers of the membrane establish communications between the canal of Petit and the anterior chamber and the region behind the lens (post-lenticular space, p. 1002).

THE MECHANISM OF ACCOMMODATION

Light rays from an object at infinity, which is taken as any point more than 20 feet distant, are parallel and are brought to a focus (principal focus) on the retina of the emmetropic eye. Rays from a near object are divergent, but they too are brought to a sharp focus. This adjustment of the dioptrics of the eye whereby it is able to focus the image of both far and near objects is called *accommodation*. That the refracting power of the eye does actually undergo a change when it is turned from a far to a near object or vice versa was shown by Scheiner (1619) by a simple experiment. A card with two pin-holes separated by a

FIG. 452. Illustrating Scheiner's experiment. o represents position of needle; ee, pinholes in card; RR, screen with image of needle focussed at I. When the screen is moved forward or backward ($R'R'$ or $R''R''$) two images ($e'f'$ and $f''e''$) appear. In the case of the eye, a double image of the needle is seen if the sight is accommodated for a farther or nearer object. The image of the needle is focussed behind the retina (represented by $R'R'$) in the first instance, and in front of the retina (represented by $R''R''$) in the second.

FIG. 453. Purkinje-Sanson images. A, during far vision; B, during accommodation for near vision. (Redrawn and modified from Williams.)

distance less than the diameter of the pupil is held before one eye. The eye is focussed upon a needle held in front of the card and perpendicular to a line joining the two holes. The needle appears single; but it appears double if the eye is focussed upon an object placed either beyond it or between it and the eye. The explanation will be evident from fig. 452.

There are at least three possible means by which accommodation of the eye could be brought about. The retina might be moved towards or away from the lens, i.e., the eye might be elongated or shortened so that divergent rays in the one instance or parallel rays in the other would be accurately

focussed. This mechanism is actually made use of in the mollusc pecten. That it is not the method followed by the human eye was disproved by Young (1801). A second possibility is that the distance between the retina and the lens is altered by a movement of the lens; this is the method used in photography, the distance between the film and the lens can be nicely adjusted for the focus of near objects. In the bony fishes accommodation is effected in such a manner.⁴

Variations in the convexity of the crystalline lens and consequently of the converging power is the third alternative. This is the method first suggested by Young for the human eye; the conception was later elaborated by Helmholtz. That

FIG. 454. The phakoscope. Description in text (footnote 5). (After Helmholtz.) Reflections from cornea (a), anterior surface of the lens (b) and posterior surface of the lens (c) during far (left) and near vision (right).

such is the mechanism adopted by mammals in general is now almost universally accepted. A change in the convexity of the anterior surface of the lens during accommodation is a well-established fact and one which can be demonstrated by

⁴ These fish are myopic when the eye is at rest, i.e., the eye is adjusted for near vision; accommodation for far vision is an active process consisting of contraction of a structure called the campanula which moves the lens backward. In some birds the central part of the anterior surface of the lens moves forwards into the pupillary aperture and as a result of pressure against the rigid margin of the iris becomes highly convex. In other avian species the cornea consists of two lamellae, the posterior being drawn backwards during accommodation for far vision. In others again (owls and hawks) the curvature of the cornea is increased during near vision.

the following experiments. A lighted candle is held to the outer side and a little in front of the eye of a subject in a darkened room. Three images (Purkinje-Sanson images fig. 453), within the subject's pupil, will be seen by an observer, one bright and erect reflected from the cornea, another larger, erect and less well-defined from the anterior surface (epithelial layer) of the lens which like the cornea, acts as a convex mirror. The third image is inverted, dim and smaller than the other two; it is reflected from the posterior (concave) surface of the lens. The subject is directed to gaze into the distance while the positions of the images are noted; he then looks at a near object when a change in the size and position of the reflection from the anterior surface of the lens will be observed. It becomes smaller and moves towards the corneal image which, of course, remains stationary. This must mean that the anterior surface of the lens has become more convex. The third (inverted) image shows little change in size or position.⁵ Now, if one knows the radius of curvature of the cornea, which can be measured by means of an instrument known as an ophthalmometer, then the radius of curvature of the surfaces of the lens and the changes in their curvature during accommodation can be calculated from careful comparative measurements of the sizes of the images from the cornea and lens. The average values for the radius of the anterior surface of the lens in five subjects examined by Fincham were 12.2 mm. for the "resting eye" and 6.8 mm. during accommodation for near vision. The change in curvature of the posterior lens surface was slight (about 0.5 mm.). The average increase in thickness of the central part of the lens was 0.47 mm., while the equatorial diameter diminished by 0.5 mm. The center of the anterior surface moved forward by from 0.3 to 0.4 mm. In general terms the change in shape of the lens during accommodation for near

vision can be summed up as follows. The central part of the anterior surface becomes more convex; the posterior surface shows little change. The peripheral region of the anterior surface actually becomes somewhat flatter, this surface taken as a whole therefore assumes a hyperbolic form.

The manner in which the change in shape of the anterior surface of the lens is brought about was explained by Helmholtz as follows. When the eye is accommodated for distant vision the suspensory ligament which, as we have seen, is attached to the lens capsule, is drawn taut as a result of the pull of the elastic structures, e.g., the ciliary body and choroid. The peripherally directed traction exerted upon the lens capsule through the suspensory ligament results in flattening of the curvature of the anterior surface of the lens. Focussing the image of a near object is accomplished by contrac-

FIG. 455. Illustrating the mechanism of accommodation of the eye for near vision. The horizontally shaded lens and the unshaded iris show the position of the parts when at rest; the vertically shaded lens and iris show the position during accommodation for a near point. C, ciliary muscle; S.L., suspensory ligament (Redrawn from Landolt.)

tion of the ciliary muscle which, by drawing the choroid forward, permits the ciliary processes to move forward and inward, thus reducing the diameter of the ring (corona ciliaris) which they form. The suspensory ligament and lens capsule are thus relaxed, and the lens, by virtue of its inherent elasticity, assumes a more convex form (fig. 455). The excised lens, i.e., one released from the restraint of surrounding structures, is therefore at its maximum convexity. Helmholtz's conception is supported in its main tenets by modern work. The movement inward of the ciliary processes during accommodation for near vision has been observed in the living human eye; and in an eye from which the lens substance had been adsorbed as a result of injury, tightening and slackening of the empty capsule was seen during the corresponding phases of accommodation. Yet the curvature assumed by the anterior surface of the

⁵ The *phakoscope*, an instrument invented by Helmholtz, may be employed for observing the images. It consists of a small hexagonal dark box (fig. 454) with an aperture (A) for the examiner's eye and another for the eye of the subject. A candle placed in front of the prisms, P and P' throws a pair of images (squares of light) upon each of the three reflecting surfaces of the observed eye. The aperture for the subject's eye is in the side of the box opposite to the window C. While his eye is being observed the subject gazes into the distance and then accommodates for near vision by fixating a needle placed in front of the window. This method of observation has the advantage that it is easier to detect a change in the distance between a pair of squares (which, of course, will indicate a corresponding change in size of the double image) than a change in size of a single image such as that of a candle flame.

lens is, as mentioned above, *hyperbolic*, whereas one would expect it to assume a spheroid form were the lens substance itself elastic and the change in shape due simply to its recoil when released from restraint.

The details of the mechanism with respect to this point have been elucidated by the work of Fincham. According to this observer, the change in shape of the lens during accommodation is explained by the high elasticity of the lens capsule and of the regional variations in its thickness (p. 994), together with the pliable nature of the cortical part of the lens as compared with the nucleus. When the lens is accommodated for distant vision, its substance is confined under tension within the capsule and, as a consequence, distends the latter to the greatest degree where it is weakest, (i.e., thinnest) namely, on the posterior

FIG. 456. The amplitude of accommodation at different ages. A. The lowest physiological values. B. Average values. C. Maximum values. (After Duane.)

surface. The convexity of this surface is therefore near its maximum when the eye is adjusted for distant objects and little further change can occur during accommodation for near vision. Upon contraction of the ciliary muscle and the consequent slackening of the suspensory ligament the recoil of the elastic capsule moulds the plastic cortex; the peripheral part of the anterior surface is thus pressed back by the relatively thick capsule but the thinner central part of the latter permits the lens substance, chiefly the highly convex nucleus, to bulge forwards.

THE VISUAL AXES AND PUPILLARY DIAMETER DURING ACCOMMODATION. The complete act of accommodation for a near object comprises, besides an increase in the convexity of the lens, *convergence of the eyes* and *constriction of the pupil*. The constriction of the pupil which occurs during accommodation serves two purposes. The nar-

rowed aperture of the iris reduces chromatic and spherical aberration (p. 999), thus increasing visual acuity, and diminishes the quantity of light (which is relatively greater from near objects) entering the eye.

The range and amplitude of accommodation. The farthest point from the eye at which an object can be seen clearly is called the *far point* or *punctum remotum*. The corresponding point nearest the eye is termed the *near point* or *punctum proximum*. In the emmetropic eye the far point is at infinity, i.e., at a distance of over 20 feet (6 meters) and the near point at from 7 cm. to 40 cm., depending upon age (fig. 456). The difference between the far and the near point distances is termed the *range of accommodation*. The difference between the refracting power of the eye when accommodation is completely relaxed for the far point and fully displaced for the near point is called the *amplitude of accommodation*. The far point is conjugate to a point on the retina, i.e., parallel rays entering the eye come to a focus on the retina and rays from the latter upon emerging from the eye are parallel and would meet at infinity. In the accommodated eye the near point is conjugate with a point on the retina. The focal length of the eye in each state of accommodation therefore corresponds, respectively, to the far and near point distances. It will be recalled that the refractive power is expressed as the reciprocal of the focal distance, the unit being 1 meter and called a diopter. The reciprocal of the far point distance is termed the *static refraction* (designated R) of the eye, and that of the near point distance, the *dynamic refraction* (P). The difference between the two (P-R) gives in diopters the amplitude of accommodation. In the emmetropic eye, since the far point is at infinity, the static refraction is taken as zero. When the near point is at 10 cm. the dynamic refraction is $\frac{100 (1 \text{ meter})}{10} = 10 \text{ D}$. The amplitude of accommodation in such an emmetropic eye is therefore 10 D.

The amplitude of accommodation diminishes progressively from childhood to about sixty years of age being 16 D at twelve years, 6.5 D at the age of thirty and only about 1 D at sixty. In other words, with advancing years the near point gradually recedes from the eye and at sixty years of age an object must be 1 meter distant in order to be clearly focussed upon the retina (see *presbyopia*, p. 1000). This phenomenon is due in the majority of instances to physical changes in the properties of the lens and its capsule (reduced plasticity of the one or diminished elasticity of the other); it occasionally results from weakness of the ciliary muscle.

THE METABOLISM AND COMPOSITION OF THE LENS. The lens is entirely epithelial in structure and devoid of blood vessels; it receives its nourishment from the fluids bathing its surfaces, e.g., the aqueous humor and

the fluid of the vitreous. The capsule acts as a semi-permeable membrane which separates substances of high osmotic pressure (equiv. 1.2% NaCl) within the lens from the osmotically less active aqueous. During accommodation, when the pressure within the lens is around that of the general intraocular pressure, fluid presumably would as a result of this higher osmotic pressure pass inwards across the capsule; on the other hand, when the ciliary muscle is relaxed as a reverse movement of fluid is to be expected, for the tension exerted upon the capsule will, by raising the intra-lenticular pressure reverse the pressure relationships and drive fluid out.

As one might expect the metabolism of the lens is low; Adams has demonstrated a small but definite oxygen uptake (30 cu. mm. per gram of lens per hour). An autoxidation system has been shown by Goldschmidt and by Adams; this consists of (1) *glutathione* which is in high concentration in the lens as compared with other tissues and (2) a *thermostable protein residue* identified as β -crystalline. These two are maintained in chemical equilibrium by an oxidation-reduction of the SH \rightarrow SS type. Though other tissues possess such an autoxidative system, in them it plays a secondary rôle, whereas in the respiration of the lens it is believed to be of paramount importance.

Four types of protein have been identified in the lens substance, (a) a *euglobin* or "*albuminoid*" (17%) which is water-soluble, and two water-soluble proteins—*pseudoglobulins*, (b) α -crystalline (11%) and (c) β -crystalline (6%), together with (d) a small quantity of albumin (0.2%). The albuminoid is present mainly in the nucleus, α -crystalline chiefly in the superficial part of the cortex and β -crystalline in the deeper parts. The two crystallines are particularly rich in the sulphur-containing amino-acids cystine and cysteine. The lens proteins as first shown by Uhlenhuth are *organ specific* not species specific, thus differing in their immunological behaviour from red cells (p. 49) and blood serum. For example, a solution of lens protein when injected into an animal of the same or of another species causes the production of an antibody—a *precipitin*. This anti-serum has then the power to precipitate a solution of lens protein from wherever derived, i.e., from a species other than the one which supplied the anti-serum, from the same species or even from the same animal.

The lens substance contains a high concentration of potassium—400 mgm. per 100 grams of wet weight—as compared with about 3 mgm. per cent in the aqueous and 20 mgm. per cent in serum. The concentrations of calcium (5 mgm. per cent), sodium chloride (300 mgm. per cent) magnesium and silicates are relatively low. The total salt concentration is between 0.7 and 0.8 per cent. Cholesterol and phosphatides amount to about 200 mgm. per cent in young lenses, but are from two to four times this value in older specimens.

CHANGES IN THE LENS WITH AGE—CATARACT. The loss of plasticity and elasticity of the lens with age as a result of a gradual sclerosis, and the

effect such changes have on the mechanism of accommodation are referred to on p. 999. Some alterations in lenticular color may accompany the sclerosing process; amber tinting, or even a reddish or brownish discoloration of the lens with consequent filtering of the shorter rays, is of common occurrence.

Cataract is the name given to any partial or complete opacity of the lens. In the commonest variety no ocular or general disease which can be held responsible precedes the development of the opacity, and this, since it appears to be simply a manifestation of age, is termed *senile cataract*. The process leading to the opacity is degenerative in nature, not inflammatory for the lens is, as just stated, avascular. The opacity commences usually in the deeper part of the cortex and does not, as a rule, involve the nucleus. The lens swells as a result of accumulation of fluid between the fibers, the anterior chamber becoming shallow. So long as the superficial layers of the cortex are clear the cataract is called *immature*. It is said to be *mature* when the opacity has extended to include the superficial layers.⁶ The water content of the lens has by this time returned to normal. The mature stage is followed by disintegration of the cortex which becomes softened into a pulsataceous mass; this is the stage of hypermaturity; drying and shrinkage of the lens finally result.

The essential change in the cataractous lens is a progressive coagulation of the lens proteins. According to the most generally accepted explanation, such a process is due to the prolonged action of ultraviolet light, and, in some instances, to the thermal effect of infra-red rays. The lens as already pointed out (p. 960), by absorbing a large proportion of the rays between λ 400 m μ and 300 m μ protects the retina from their injurious effects. Wave lengths below 297 m μ are absorbed by the cornea. The rays absorbed by the lens are not without their effect upon the lens substance itself; it is these which cause the physical change in the lens proteins. Two stages are recognized in the coagulation process, (1) *denaturation of the lens proteins*, consisting presumably of a molecular rearrangement, by light or heat which renders them susceptible to (2) *aggregation (agglutination) of the protein particles* into a flocculent mass—coagulation. This ultimate result occurs only in the presence of certain salts and is enhanced by some organic substances, e.g. dextrose and acetone. The theory that radiant energy is responsible for denaturation of the lens proteins is in accord with many observations. For example, the absorption by the lens of the shorter rays increases with age. The

⁶ As long as a clear interval exists between the opacity and the iris (which lies in contact with the anterior surface of the lens) the latter throws a shadow upon the former. When the opacity involves the entire thickness of the cortex, i.e., right up to the iris, there is no shadow.

opacity commences in the lower quadrant of the lens which receives the most intense light. In tropical countries, e.g. India and Egypt, cataract is much commoner than in temperate latitudes; it is also less frequent in the latter than in Arctic zones, presumably as a result of the high content in acitinic rays of the light reflected from snow and ice. It is also stated that on this continent the incidence of cataract increases from temperate zones to the equator, and that it is also higher in those who work in the fields than in city dwellers. Burge's experiments and the more recent ones of Clarke show convincingly the effect of light upon the development of lenticular opacities. Burge found that whereas exposure of a solution of lens protein to ultraviolet light for 100 hrs. did not cause coagulation, this occurred if CaCl_2 , MgCl_2 , dextrose or acetone were added. Moreover the exposure of the eye of a living fish or frog to short light waves was without effect if the animal had previously been kept in tap water, but definite opacity of the lens followed a few hours exposure, if the fish or frog had been for some days in water containing 0.8% calcium chloride, 0.1% dextrose or 0.1% sodium silicate. Clarke found that heat enhanced the action of the light rays upon solutions of lens proteins, and that opacity could not be produced in the absence of calcium.

The incidence of cataract is much higher in diabetics than in normal persons; it is usually of the ordinary or so-called senile type, but it occurs at an earlier age. The opacity is attributed to the action of dextrose and possibly of acetone bodies in rendering the lens proteins more readily coagulable by light. Duke-Elder believes that as a result of the high blood sugar, the osmotic relationships between the lens and the surrounding fluids are disturbed and the nutrition of the lens thereby interfered with.

Though the factors outlined above appear to be the main ones concerned in the production of the common or senile type of cataract, opinions differ considerably as to the details of the mechanism involved, as well as in regard to the production of other types of lenticular opacity. It is suggested, for example, that the action of ultraviolet rays in inducing denaturation of the lens proteins is due to the reduction of the glutathione and β -crystalline content and the consequent depression of the autoxidative mechanism. Such an effect of ultraviolet radiation has been shown experimentally; it has also been established that the content of the lens in glutathione and in the thermostable protein residue diminishes with age. The power of the lens to fluoresce upon exposure to short wave radiations (p. 960) and the disposal of the surplus energy by converting them into long waves, is considered by Burge to be an important factor in ameliorating the effect of light upon the lens; fluorescing bacteria for example are much less readily killed by ultraviolet light than are other types. It is of some considerable interest therefore that the power of the lens to fluoresce diminishes with age. In glass blowers' cataract, infra-red rays would

appear to play an important auxiliary rôle. Hartridge and Hill believe that these act indirectly by increasing the production of aqueous humor by the ciliary processes and iris which leads to disturbances in the fluid interchanges between the lens and its surroundings, the nutrition of the lens suffering as a result. They point out that the lens absorbs only about 12% of the heat rays which enter the eye whereas the iris absorbs all which reach it; it is unlikely, therefore, that their action upon the lens proteins is direct. Heat rays may act, however, simply by accelerating the denaturing action of ultraviolet light (Clarke). Duke-Elder, on the other hand, suggests that the heat rays affect the permeability of the capsule, with consequent upset in the osmotic relationship between the lens substance and the aqueous.

An interesting type of cataract is that following parathyroidectomy; disordered calcium metabolism would appear to be in some way concerned in its production; the calcium content of the lens is increased, whereas that of the blood is reduced. There is no definite evidence, however, to connect ordinary senile cataract with parathyroid deficiency, but there seems little doubt that calcium is concerned in some obscure way with cataract development. A favorite method of producing cataract for experimental study is by the injection of naphthaline; opacities form only if the animal is on a low calcium diet. In rats, lenticular opacity is readily produced by a diet containing a high percentage of lactose or galactose; the former sugar increases the absorption of calcium, but whether this fact has any bearing upon the development of the cataract is difficult to say; it does not dovetail with other observations in respect to calcium and the development of cataract.

The composition of the cataractous lens shows marked differences from the normal. There is an increase in the insoluble albuminoid and a decrease of the soluble proteins and of glutathione; the oxygen uptake is much reduced. Of the inorganic constituents calcium shows a relatively enormous increase (up to 140 mgm. per cent). The concentration of magnesium, sodium and silicates is also raised, whereas that of potassium is greatly reduced.

OPTICAL DEFECTS

SPHERICAL ABERRATION. Rays traversing the peripheral parts of an ordinary convex lens are refracted more strongly and therefore come to a focus nearer the lens than do those transmitted through more central regions. In other words, the outer and inner rays cross in front of the retina and a blurred image is formed (fig. 457). This is an inherent defect of convex lenses and is called *spherical aberration*; in the manufacture of a camera lens, special means are employed to correct it, the lens being built up of separate pieces of glass of different refractive indices cemented together so that all rays are converged to the same point.

Spherical aberration is corrected in a somewhat similar manner in the crystalline lens, the nucleus having a higher refractive power than the periphery (see p. 986). The iris, since it covers the outer part of the lens and shuts off the peripheral rays, also serves to correct this defect.

CHROMATIC ABERRATION. The colors composing white light are refracted to different degrees according to their wave lengths. The violet rays are refracted most, the refractibility diminishing progressively from the violet to the red end of the spectrum (fig. 458). For this reason a series of fringes, colored from violet to red from within outwards, borders the image formed by a simple cheap lens. *Chromatic aberration*, as this defect is called, is corrected in camera and microscope lenses by cementing a biconvex lens of crown glass to a

FIG. 457. Spherical aberration. Outer rays meet at 1, inner rays at 2.

FIG. 458. Chromatic aberration.

concave one of flint glass. Such a lens is called *achromatic*. The lens of the eye is only partially corrected for chromatic aberration (p. 986). A red and a violet object at the same distance from the eye therefore cannot both be seen sharply at the same time. If, for example, the eyes are focussed upon a violet light, they must accommodate, in order to maintain the focus, when the light is changed to red. In ordinary vision the colors surrounding the images on the retina are not perceived; we have come to ignore them.

Diffraction and the scattering of light within the eyeball. Light is diffracted by the pupillary margin and by the lens fibers and corneal epithelium; as a result of this and of spherical aberration the retinal image is not made up of points of light but of diffusion circles (blur circles),

i.e., a bright central disc surrounded by light rings which diminish in intensity by almost imperceptible gradations towards the periphery. The relative size of the central bright area varies inversely with the diameter of the pupil and directly with the wave length of the light. The opposite effects of changes in the size of the pupil upon this defect and upon chromatic aberration have been pointed out (p. 983).

None of the ocular media is perfectly homogeneous; owing to their colloidal nature a certain proportion of the light entering the eye is scattered (Tyndall phenomenon), that is, it is not focussed upon the retina but is deflected from the course which it would follow according to the laws of refraction if the contents of the globe were perfectly transparent. The colloidal particles have a size of the order of the wave length of light. The quantity of scattered light is directly proportional to the square of the size of the particles, and inversely proportional to the fourth power of the wave length (Rayleigh). Thus the greatest scattering within the eyeball occurs with violet and ultraviolet light and the least with red. The dispersion of ultraviolet rays probably serves a useful purpose in that the retina is thus protected from their injurious effects.

PRESBYOPIA (Gr. *presbos*, old; *ops*, the eye) is the term given to the gradual reduction in the amplitude of accommodation which goes hand in hand with advancing years.

EMMETROPIA AND AMETROPIA. The four optical defects just described may be regarded as physiological, the first three being inherent to some extent in optical systems in general; the fourth is a natural accompaniment of age. Two other defects of frequent occurrence are due to incongruity between the length of the eyeball and its refracting power and must be classed as definite abnormalities.

The refractive state of the normal eye, which has its far point (p. 997) at infinity, i.e., at a distance greater than 6 meters (20 feet), is called *emmetropia*. Parallel rays entering the emmetropic eye are brought to a clear focus on the retina without any effort of accommodation. The static refraction (p. 997) of such an eye is therefore zero. If the far point is not at infinity the eye is *ametropic*. There are two forms of ametropia—myopia and hypermetropia (fig. 459).

In *myopia* (Gr. *myo*, I blink or half close the eye; *ops*, the eye) or *short sight*, the eyeball is too long relatively to its refracting power (fig. 459, B). Obviously, such an eye will bring parallel rays to a focus in front of the retina, i.e., in the vitreous. After meeting, the rays cross and form a blurred image or a diffusion circle upon the retina, just as a camera which is extended too far forms an indus-

tinct image upon the film. In order to form a clear image on the retina of the myopic eye the rays must be, not parallel but divergent; such as are emitted by a near object. The far point is therefore at a finite distance, and in extreme instances may be only a few centimeters from the eye. Accommodation, of course, is relaxed for the far point as in the emmetropic eye for, obviously, increasing the converging power of the lens will only cause greater blurring of the image. The far and near points being close together, the range and the amplitude of accommodation (p. 997) are reduced. Myopia is corrected by means of concave (diverging) lenses. If, for example, an object can be seen clearly no farther away than 1 meter, the myopia is -1 D, i.e., a concave lens of this power is required.

In *hypermetropia* (Gr. *hyper*, above; *metros*, measure; *ops*, the eye) or *long sight* (fig. 68C) the eye is too short for its refracting power.⁷ There-

FIG. 459. A, emmetropia; B, myopia; C, hypermetropia.

fore parallel rays after refraction fall upon the retina before they have come to a focus, and form an image blurred by diffusion circles. The far point lies, as it were, "beyond infinity" and is *virtual*, i.e., it is behind the eye at the point where the rays would meet if continued backwards through the retina. The hypermetrope must accommodate when he views distant objects in order to focus the parallel rays upon the retina. The range of his accommodation (p. 997) is the same as that of the emmetrope but the amplitude is greater. Suppose, for example, that the near point is 0.10 meter in front of the eye and the far point is 0.25 meter behind, i.e., negative (-0.25).

Then the dynamic refraction is $\frac{100}{10} = 10$ D, and

⁷ Both types of ametropia in the great majority of instances are due to an abnormality in the length of the eyeball and not to any change in the refracting power of the eye.

the static refraction is $\frac{-100}{-25} = -4$ D; the amplitude of accommodation is therefore 10 D $- (-4$ D), or 10 D $+ 4$ D = 14 D. Hypermetropia is corrected by means of a convex lens, the distance of the far point behind the eye giving the measure of the strength of lens required; if this is -0.25 meter then a $+4$ D lens would correct the defect (see p. 991). The larger amplitude of accommodation in hypermetropia is accompanied by hypertrophy of the ciliary muscle; in myopia, on the other hand, the muscle shows atrophy and the circular fibers may be absent.

ASTIGMATISM (Gr. *a*, privative; *stigma*, a point). In this condition, as its name implies, rays of light are not brought to sharp points upon the retina, but form short lines. The defect is present in all eyes to a certain degree, and it is only when pronounced that it can be considered abnormal.

FIG. 460. Showing course of rays in an astigmatic eye. The curvature of the cornea is greater in the vertical meridian *vvv* than in the horizontal meridian *hhh*. Hence the rays of light coming from the point *P* and passing through the vertical meridian come to a focus at *f*¹, while those through the horizontal meridian come to a focus at *f*². (After Waller.)

It must be remembered that rays of light pass through all meridians of a lens; in converging to a focus they therefore form a cone of light, not simply a flat pennant-like beam. If all meridians of a lens have the same curvature, then rays in all planes will be refracted to the same degree and come to a focus together. If, on the other hand, the curvatures differ, the rays transmitted through a meridian with the greater curvature will be refracted more strongly and brought to a focus in front of rays passing through other meridians. For example, should the vertical meridian be more curved than the horizontal, then when the rays passing through the vertical meridian are in focus those in the horizontal will form, not a point, but a horizontal line (see fig. 460). Such inequalities of curvature in the meridians of the cornea or, less commonly, of the crystalline lens, are the cause of astigmatism. The greater curvature may be in either the vertical, horizontal or an oblique meridian. When the subject of astigmatism looks at a clock face, the straight lines in the vertical

numerals XII and VI may be clearly seen, while the horizontal lines in IX and III are blurred, or vice versa. Or, the diagonal numerals may be out of focus while the vertical and horizontal are sharply defined.

Astigmatism is corrected by the use of spectacle lenses convex in the meridian corresponding to that of the cornea (or crystalline lens) having the lesser curvature. Thus if the curvature of the cornea is greater in the vertical meridian, the subject is fitted with a cylindrical lens having its convexity in the horizontal meridian.

THE INTRA-OCULAR FLUIDS

THE INTRA-OCULAR PRESSURE. The pressure within the chambers of the eye of a living animal

FIG. 461. Showing the distribution of volume-pressure in the eye with (1) a collapsed blood-pressure, (2) in the normal state, and (3) with raised blood pressure and capillary dilatation. (After Duke-Elder. The nature of the intra-ocular fluids.)

is from 20 to 25 mm. Hg and from 8 mm. to 10 mm. Hg in the excised but intact globe; it also falls to the latter level immediately after death or after arrest of the ocular circulation. The difference between these two sets of values, is due to the pressure of the blood in the vessels of the globe. This will be clear from fig. 461. The vascular bed of the eyeball lies between the relatively resistant sclerotic on the outside and the incompressible intra-ocular contents on the other. It is evident that blood pumped into the vessels of the choroid will raise the intra-ocular pressure above that of a bloodless eye. The intra-ocular pressure runs closely parallel with that of the blood in the choroidal capillaries. A rise or fall in general arterial pressure therefore may cause a corresponding change in intra-ocular pressure, though

it will be much less in degree. The pulse beat causes a variation in intra-ocular pressure of from 1 to 2 mm. Hg, and the respiration one of from 3 to 5 mm. Hg. However, since it is the pressure in the capillary bed of the eye rather than that in the larger ocular vessels which is the determining factor and the former pressure can vary as a result of *local* changes in caliber of the minute vessels, the intra-ocular and arterial pressures do not necessarily change in the same direction. Thus arterial hypertension, in which the capillary pressure is not raised (p. 134), does not cause a rise in intra-ocular pressure; amyl nitrite, on the other hand, causes a *fall* in arterial pressure as a result of the peripheral vasodilatation, accompanied by a *rise* in intra-ocular pressure (due to the dilatation of the capillaries of the eye and the consequent increase in capillary pressure). The intra-ocular pressure therefore follows very closely the venous pressure; tying the vortex veins, for example, increases capillary pressure and causes a rise in intra-ocular pressure of from 50 to 60 mm. Hg. The pressure of 8 or 10 mm. Hg which, as mentioned above, exists within an eye immediately after its circulation has been arrested, may be looked upon as representing the balance struck between the production of intra-ocular fluid and its removal through the drainage channels (p. 1003).

Other factors which affect the intra-ocular tension are, pressure from without by the action of the eyelids and of the extrinsic muscles of the eye. The effect exerted by the eye muscles in ordinary movements is negligible, but maximally strong convergence of the eyeballs may raise the pressure by from 4 to 10 mm. Hg. Movements of the lids have a greater influence, strong contraction of the orbicularis oculi causing a rise of 50 mm. Hg or more. Exposure of the eye to light causes a fall, and dark adaptation a rise in pressure which is attributed to constriction and dilatation, respectively, of the ocular capillaries. Contraction of the ciliary muscle causes no change in the intra-ocular pressure, nor does the state of the pupil. A change in pressure does not occur therefore upon accommodation of the eye, provided that the associated convergent movement is prevented.

THE VITREOUS BODY. The vitreous body occupies the segment of the globe lying behind the lens and the ciliary processes. In front it presents a saucer-shaped depression—the *hyaloid fossa*—which lodges the posterior convexity of the lens. A narrow space (*post-lenticular space*) filled with fluid separates the lens from the concave surface of the vitreous. The *hyaloid canal* (which lodged the hyaloid artery in the embryo) runs from the posterior pole of the lens to the center of the optic disc. The structureless *hyaloid membrane* sur-

rounds the vitreous; anteriorly it is strengthened by radial fibers which have already been referred to as the *zonula ciliaris* (p. 994). In this region it shows a series of grooves which lodge the ciliary processes. The vitreous body is a jelly-like material, possessing no obvious structure; but it is claimed that by the use of special fixatives (e.g., a weak solution of chromic acid) a series of superimposed lamellae arranged concentrically around the hyaloid canal and composed of very thin flat cells can be demonstrated. The spaces between the lamellae contain fluid almost identical in composition with the aqueous humor. Though some maintain that the lamellae are fixation artefacts and that the vitreous body is a homogeneous gel, there seems little doubt that a framework does exist. Friedenwald and Stiehler observed it in the vitreous of ox eyes which had been prepared without the use of fixatives. The structural framework contains a protein called *vitrein*. The refractive index of the vitreous is 1.33 (see p. 986).

The AQUEOUS HUMOR is a clear watery fluid occupying the anterior and posterior chambers of the eye. It has a refractive index of 1.33; it is alkaline in reaction (pH 7.1–7.3), has a specific gravity of from 1002 to 1004 and a viscosity of 1.029. Its composition and that of serum are given in the following table, after Duke-Elder.

	Grams per 100 cc. Aqueous humor	Serum
Water	99.6921	93.3238
Solids.....	1.0869	9.5362
Total protein.....	0.0201	7.3692
Albumen.....	0.0123	4.4135
Globulin.....	0.0078	2.955
Fibrinogen.....	—	—
Fats.....	0.004	0.13
Reducing sugar.....	0.0983	0.0910
Non-protein nitrogen.....	0.0236	0.0239
Inorganic constituents Na, K, Ca, Mg, Cl, P and S.....	0.7529	0.7433

The chief differences between the compositions of serum and aqueous are shown in the concentrations of substances of colloidal nature—the proteins and fats. The diffusible non-ionizable substances, such as urea and other non-protein nitrogenous constituents and sugar, are in almost the same concentrations in the two fluids. Chloride is unequally distributed in the aqueous and the serum, the former having a considerably higher concentration; this point will be discussed in the next section.

THE FORMATION OF THE INTRA-OCULAR FLUIDS.

There have been three theories proposed in respect to the formation of intra-ocular fluid, namely, that the process is one of (a) *dialysis*, (b) *filtration* or (c) *secretion*. The results of the experiments of Duke-Elder and his associates upon the concentrations of electrolytes in the aqueous humor and in the blood serum leave little doubt that the proc-

ess is one of dialysis. They found that the distribution of the ions Na, K and Cl between the two fluids is in accordance, approximately, with that demanded by Donnan's equilibrium theory (p. 103) and with the laws of simple dialysis. In experiments upon the surviving heads of cats perfused with cat's blood containing an excess or a deficiency of one or other of these ions the permeability of the membrane separating aqueous humor and blood was approximately the same before as after poisoning with cyanide, and the same as in the normal animal. Such results seem definitely to exclude a secretory process.

The surface of the ciliary body and the posterior aspect of the iris are believed to constitute the membrane interposed between the aqueous humor and the blood. That diffusion occurs across *both* these surfaces is indicated by the following observations. When the pupillary aperture is occluded either experimentally or as a result of disease, aqueous fluid accumulates behind the iris. On the other hand, fluid is formed after excision of the iris or when it is congenitally absent. In certain fish not possessing a ciliary body and in the congenital absence of the latter in man, normal aqueous humor is present; it has also been found in a cyst of the iris itself.

THE CIRCULATION OF THE INTRA-OCULAR FLUIDS. THE DRAINAGE SYSTEM OF THE EYE. Intra-ocular fluid is probably reabsorbed to some extent from all parts of the interior of the globe. A small proportion of the secreted fluid passes from the posterior chamber through the zonule and down the hyaloid canal to the lymphatics of the optic nerve. However, less than 1 per cent is reabsorbed in this way, or indeed from any region of the eye lying posterior to the iris. The chief exits for the fluid are at the angle of the anterior chamber (*angle of the iris* or *filtration angle*) and from the anterior surface of the iris. It will perhaps be of advantage to the reader if the main structural features of this region are recalled.

On the deep aspect of the sclera at its junction with the cornea and in front of the angle of the anterior chamber lies an annular venous sinus—the *canal of Schlemm* (*sinus venosus sclerae*) (fig. 448). The sinus completely surrounds the corneal margin and in meridional sections of the eye appears as a small oval gap or cleft lined by endothelium. The inner or posterior wall of the canal is separated from the anterior chamber by a zone¹ of trabecular tissue formed by the breaking up of the posterior elastic lamina of the cornea and termed the *pectinate ligament*; the intervals between the trabeculae are termed the *spaces of Fontana*. The tra-

becular tissue of the pectinate ligament is continued around the irideal angle, its fibers terminating in the tissue of the iris. Schlemm's canal is fed by an *afferent arteriole* derived from the ciliary arteries and drained by an *efferent venule* which empties into the episcleral venous plexus (Friedenwald). The spaces of Fontana communicate with the anterior chamber, but there is no *direct* communication between the former and the lumen of Schlemm's canal; the canal cannot be injected, for example, with a colloidal solution introduced into the anterior chamber.

The *scleral spur* is the term applied to a small triangular projection of the sclera on the posterior aspect of the sclerocorneal junction; it lies immediately behind the outer part of the posterior wall of Schlemm's canal and gives attachment to the meridional fibers of the ciliary muscle. Contraction of the muscle, by pulling upon the spur, is said to dilate the canal and thus favor the drainage of fluid from the anterior chamber.

Movement of the intra-ocular fluid from the posterior to the anterior chamber and from the latter to the filtration angle is brought about largely through intermittent variations in intra-ocular pressure occasioned by the several factors already discussed (e.g., pulsatile and respiratory variations in blood pressure and actions of the eyelids, etc.). Temperature differences between the superficial and deeper parts of the anterior chamber (*thermal factor*) cause convection currents to be set up which also play an important part in the movement of fluid. At the angle of the iris the fluid percolates into the spaces of Fontana whence it is absorbed across the posterior wall of the canal of Schlemm.

Friedenwald and Pierce have demonstrated a differential absorption between the water, crystalloids and protein constituents of the aqueous. From their experiments which involved the introduction of substances into the anterior chamber, these observers conclude that crystalloids and a small quantity of water are reabsorbed from the anterior surface of the iris, passing by diffusion through the walls of the capillaries. Colloids are removed by the phagocytic action of the surface layer of epithelial cells. A part of the protein is hydrolyzed by the action of enzymes present in the fluid and reabsorbed as amino-acids. Water is absorbed chiefly through the spaces of Fontana and the canal of Schlemm. The rate of passage of fluid through the wall of the canal is governed apparently by hydrostatic and osmotic forces. The pressure of blood in Schlemm's canal (or rather in the small veins leading from it) is stated to be equal to or about 1 mm. higher than that of the fluid in the anterior chamber, but after the absorp-

tion of crystalloids one would expect the osmotic pressure of the aqueous to be considerably lower than that of the serum; under such circumstances an uptake of fluid would occur, provided the blood flow through the canal did not fall below a certain level. Slowing of the circulation would tend (as a result of the dilution of serum colloid dilution by the reabsorbed fluid and consequent reduction in osmotic pressure) to reduce the rate of reabsorption, an increase in blood velocity to increase it. Such a relationship was actually observed by Friedenwald and Pierce. Increase in intra-ocular pressure would quite evidently increase reabsorption, the pressure would thus tend automatically to be restored to its original level.⁸

GLAUCOMA OR OCULAR HYPERTENSION. Persistent elevation of the intra-ocular pressure occurs as an accompaniment of several diseased states of the eye and may then be due to blockage of the drainage channels at the iridial angle or to the excessive production of fluid. The latter effect may result from mechanical irritation of the ciliary processes (e.g., by displacement of the lens) or obstruction of the venous channels with consequent rise in capillary pressure. Ocular hypertension associated with some such obvious disease of the eye is referred to as *secondary glaucoma*. When the intra-ocular pressure is persistently elevated above 35 mm. or so and no abnormality of the eye exists to account for the hypertension, it is termed *primary glaucoma*. At the outset it may be said that, though primary glaucoma has been the subject of much speculation, its cause remains obscure.

The excessively high intra-ocular tension causes compression of the vessels and in time serious disturbances in the nutrition of the eye result, namely, optic atrophy, excavation ("cupping") of the disc, blindness and ultimately disintegration of the optical mechanism. Owing to the readjustments which take place in the ocular circulation the hypertension may exist for some time before any of these effects make their appearance. The pressure as it gradually rises first compresses the venous channels but, as a result of the opening up of the arterioles and capillaries, a larger proportion of the arterial pressure is transmitted to the venous side; the compressing force is thus overcome and the circulation

⁸ According to some authorities (Maggiore, Duke-Elder) the canal of Schlemm contains blood only when the ocular venous pressure is inordinately high, being filled under usual circumstances with an aqueous fluid (with an osmotic pressure around that of the fluid in the anterior chamber). Since, as mentioned above, the pressure of blood in the small veins leading from it is higher than the normal intra-ocular pressure the canal could not serve as a pathway for the continued reabsorption of fluid; it is claimed that reabsorption can occur only if the intra-ocular pressure rises above the normal level. This conception attributes a safety-valve function to the canal, i.e., it is called into play presumably only in an emergency.

maintained. This stage in the progress of the condition is referred to as *compensated glaucoma*. A point will be reached, however, at which the pressure of the intra-ocular fluids approaches equality with that in the ophthalmic artery; then further compensation becomes impossible and the structural changes just mentioned supervene. The condition is then termed *inflammatory* or *decompensated glaucoma*.

The possible factors which have been suggested in explanation of the elevated pressure will be briefly considered. Mechanical obstruction at the filtration angle, due to reduction in the depth of the anterior chamber and the consequent adhesion of the periphery of the iris to the cornea, is frequently present in decompensated cases, but this is secondary and not primarily related to the hypertension. It is not improbable that some abnormality in the nervous control of the vascular bed of the globe is fundamentally responsible. Friedenwald suggests that the reabsorption of water through the mechanism of Schlemm's canal as a result of sclerosis and narrowing of the afferent vessels (p. 1004) may be the essential factor concerned. Reduction in the caliber of these vessels would tend, by slowing the blood flow through the canal, to reduce the reabsorption rate. Spasm of the vessels feeding the sinus would have a similar effect. On the other hand, the reduced depth of the anterior chamber in decompensated glaucoma suggests that the increased pressure originates in the

posterior chamber of the eye and the theory has been advanced that swelling of the vitreous is responsible. From the gel-like nature of the vitreous body one might expect its water content to vary with changes in its inorganic constituents or in pH. It has been found, however, that the chemical changes necessary to cause any significant increase in volume of the vitreous are far greater than any that could occur in the body. Finally, a vasodilator toxin of the histamine type has been suggested which supposedly, by causing dilatation of the intra-ocular capillaries and an increase in the permeability of their walls, would lead to overproduction of intra-ocular fluid. The aqueous in decompensated glaucoma has a higher protein, and lower chloride content and osmotic pressure than normal; this fact lends some force to the theory of increased capillary permeability. The abnormal permeability would also, by reducing the effective osmotic difference between the contents of the anterior chamber and the blood, tend to diminish reabsorption. Nevertheless, analysis of the aqueous humor in *compensated* cases shows no significant departure from the normal and therefore lends no support to the idea that a change in capillary permeability is the fundamental factor in the development of glaucoma.

There is no causative relationship between arterial and ocular hypertension (see p. 1002).

CHAPTER LXXVII

THE VISUAL FIELDS AND PATHWAY. MOVEMENTS OF THE OCULAR MUSCLES. STEREOSCOPIC VISION

THE VISUAL FIELDS. The visual field of one eye is the part of the external world which is seen by that eye at any given moment, i.e., when its

FIG. 462. Showing monocular (white) and binocular (black) fields of vision. Upper rabbit; lower monkey (or man) (from Parsons, after Brouwer and Zeeman).

gaze is fixed in one direction. It may be likened to a portion of a great hollow sphere—a bowl—upon the interior surface of which the images of the external world are projected. Traquair pictures

the visual field as “an island of vision surrounded by a sea of blindness”; carrying the simile further, the surface contour of this imaginary island is described in terms of visual acuity, the highest point corresponding to the fovea, a deep (bottomless) point to the blind spot and a gradual slope to the coastline, to the peripheral retina. The visual field of each eye subtends an angle of about 160° in the horizontal and 145° in the vertical meridian. The visual field of each eye is divided by a line passing vertically through the fixation point (p. 1017) into two unequal parts, an outer or *temporal* and an inner or *nasal*. The latter is smaller owing to the shadow of the nose, its diameter being about 60° whereas the diameter of the temporal part

FIG. 463. The blind spot. Close the left eye, hold the figure about six inches in front of the right eye and look steadily at the cross. Move the book slowly toward the eye until the circle disappears. When this occurs the image of the circle has fallen upon the entrance of the optic nerve from which rods and cones are absent; it is therefore insensitive to light. Figure on the right shows the blind spot projected 6" in front of the right eye as mapped out by means of perimetry (After Helmholtz.)

around 100° . Similarly a line passing horizontally through the point of fixation divides the field into an upper and a lower part, the former being restricted by from 5° to 10° by the upper lid and orbital margin. Rays of light from the outer or temporal half of the visual field fall upon the nasal (inner) half of the retina, those from the inner or nasal half of the visual field fall upon the temporal half of the retina (fig. 467, p. 1011). Although an image is formed upon each retina the two are fused in consciousness into a single impression (See p. 1014). In most animals the visual fields of the two eyes overlap, that is, certain parts of the outside world are seen by both eyes at the same instant—*binocular vision*. In animals with eyes placed laterally in the head overlap of the visual fields must obviously be very small in extent, the

visual fields being almost completely separate—*monocular vision*. The extent of overlap of the visual fields of the monkey and of man, whose eyes are placed in the front of the head, is large (120° horizontal diameter) and the monocular field of vision, that is, the field which can be seen by one eye but not by the other, is relatively small (35°) (figs. 462 and 465). Rays of light entering the eyes from an object in the binocular field of vision fall upon the nasal half of one retina and upon the temporal half of the other. If, however, the object is well to the right or to the left of the line

two fields plus the monocular fields on each side is about 200° .

We shall see when the arrangement of the fibers conveying visual impulses is considered that fibers arising from the nasal halves of the peripheral retinas and of the maculae cross in the chiasma, whereas the temporal fibers remain uncrossed. Thus it is that the occipital cortex of one side receives impulses from the nasal half of the opposite retina and from the temporal half of the retina of the same side (fig. 467, p. 1011). Loss of vision in one half of each eye is called *hemianopia*¹ (half-blindness). When the blindness affects the right

FIG. 464. I, showing the distribution of the visual fibers in the retina (A), optic nerve (B), chiasma (C), optic tract (D) and in the lateral geniculate body (E). In D the area marked with small circles represents the fibers of upper half of peripheral retina, the crosses the lower half (redrawn from Duke-Elder, after Henschen and Brouwer and Zeeman). II, Diagram of types of hemianopia, 1, homonymous; 2, bitemporal; 3, binasal; 4, homonymous superior quadrantic.

of vision, i.e., in the outer part of either temporal field, the rays then fall upon the nasal half of the peripheral retina of the nearer eye (right or left) but not upon the other retina which is shaded by the nose. So the monocular field of vision consists in man of a crescentic area (35°) at the outer limit of the temporal field of each eye. When one looks directly at an object the eyes are turned so as to bring an image of the object upon the most sensitive area of each retina, i.e., upon the nasal and temporal halves, respectively, of the maculae luteae. The horizontal diameter of the entire visual field, that is, of the area of overlap of the

FIG. 465. Perimeter chart showing normal visual field of left eye. M, blind spot; g, r, b and w indicate boundaries of fields for green, red, blue and white, respectively. Meridians indicated by Roman numerals. (After Starling.)

or the left halves of both retinas, i.e., the nasal half of the left retina (temporal half of visual field) and the temporal half of the right (nasal half of the visual field) or vice versa, the hemianopia is said to be *homonymous*—left or right respectively. If the blindness is in the *left* half of one retina and in the *right* half of the other, i.e., in either both temporal retinal halves (nasal halves of visual fields) or in both nasal retinal halves (temporal halves of visual fields) the hemianopia is referred to as *binasal* or *bi-temporal*, respectively. It will be noted that the qualifying terms refer to the affected

¹ Hemiopia (half sight) and hemiopia are alternative terms which are sometimes used; they have practically identical meanings.

halves of the *visual fields* and not to the retinal halves. In other instances a quarter only of each visual field is affected, when the term *quadrantic hemianopia* is employed. It may be the upper or the lower quadrants of the nasal or of the temporal fields which are involved, or homonymous quadrants may be affected, i.e., a quadrant in the nasal field of one eye and in the temporal field of the other. The type of hemianopia is further specified by the use of the word "superior" or "inferior" (fig. 464). Thus, a superior nasal quadrantic hemianopia is one in which the eyes do not see objects in the upper nasal quadrants of the visual fields, (blindness of lower temporal retinal quadrants).

Isopters. The sensitivity of the retina from the periphery to the fovea can be explored by using a series of test objects of graduated sizes with the perimeter, and determining in different meridians the distance from the fixation point (p. 1017) at which each object is just perceptible. The points so determined are marked upon the perimeter chart and lines drawn through each set. Thus a series of boundary lines roughly concentric with the fovea are constructed which indicate the thresholds for the perception (minimum visible, p. 961) of the different test objects, and therefore demarcate levels of retinal sensitivity. Each is called an *isopter of sensitivity*; they might be compared to the contour lines indicating elevations on a detailed geographical map.

THE BLIND SPOT. The entrance of the optic nerve (p. 956) since it is devoid of rods and cones is completely blind. An object whose image falls upon it is therefore invisible (see fig. 463). Not even a sensation of blackness results, for when the eye is fixated upon the cross, as described in the legend of the figure, and the book moved until the optic disc is occupied by the circle the latter simply disappears, no sensation whatever being experienced to indicate its existence. Ordinarily this "hole" in the visual field causes no inconvenience because, in any position of the eyes, should one image of an object fall upon the blind spot a sensitive part of the opposite retina receives the other image. But even when one eye is closed the fine involuntary ocular movements, by constantly shifting the fixation point, though ever so slightly, keeps us completely unaware of the existence of the insensitive area. When mapped out accurately by perimetry the blind spot has the shape shown in figure 463.

THE OPTIC NERVE. The ganglion cells of the retina (ganglion cell layer) whose central processes constitute the optic nerve, are the secondary neurons of the visual pathway (p. 955). The primary neurons are the bipolar cells of the inner nuclear layer, the peripheral processes of the

latter connecting with the visual receptors—the rods and cones. Tertiary neurons complete the pathway from the lateral geniculate body to the visual cortex. The fibers of the ganglion cells as they enter into the formation of the optic nerve are arranged in groups corresponding, in their relative positions, to the quadrants of the peripheral retina from which they arise. That is, fibers from the upper and lower temporal quadrants of the retina are found in the upper and lower parts of the nerve, respectively (fig. 464). Those from the nasal quadrants are situated in the inner sections of the nerve, the fibers from the upper quadrant lying above those from the lower. The macular fibers occupy a lateral position, being wedged between the upper and lower temporal bundles, but again, fibers from the upper half of the macula lie above those from the lower half.

THE OPTIC CHIASMA. The fibers from the temporal halves of the peripheral retina continue uncrossed into the corresponding optic tracts, while the fibers from the nasal halves cross in the chiasma to the optic tract of the opposite side.² As the fibers of the optic nerve approach the chiasma the macular fibers move toward the center or "core" of the nerve. In the chiasma itself the temporal fibers lie in its lateral angle. Those of upper retinal origin lie above those arising from the lower retinal quadrant. In the crossing of the nasal fibers, those from the upper quadrants lie upon the upper aspect, those from the inferior quadrants upon the under aspect of the chiasma; the macular fibers lie in between.

Perimetry is the term applied to the procedure of mapping out the visual fields. The instrument employed is called a *perimeter*. It comprises a metal band or arm, shaped in a large arc of a circle with its concavity directed towards the subject. A holder sliding in the arc carries the test object which can be moved centrally or peripherally as required. The arm itself is pivoted at the center enabling it to be rotated to any angle. The subject's head is supported on a chin-rest. One eye is covered; the eye under examination is placed at the center of the sphere of which the perimeter arm forms the arc, and made to fix a point straight ahead in the center of the arm. The latter is rotated by degrees through a full circle and at each new position the test object is moved centrally until it is just perceived by the subject. This point and corresponding points at the various positions of the arm are marked upon a perimeter chart and the contour of the visual field outlined through them. The chart

² In animals such as the rabbit in which vision is largely monocular, the uncrossed fibers are very few in number.

(fig. 465) is ruled in circles (comparable to latitudes on a geographical map) to indicate degrees from the point of fixation, and in radiating lines ("longitudes" or meridians). The mapping of the blind spot and of the sensitivity of the retina in isopters has been referred to. The reader should consult texts on ophthalmology for a more detailed description of perimetry. A simple but rough method of perimetry (*confrontation method*) which will reveal a major limitation of the visual fields is the following. The observer stands facing the subject and about two feet in front of him. The patient covers one eye while the other, which he fixes upon the opposite eye of the examiner, is being tested. The examiner holds his finger midway between himself and the patient but outside the limit of his own visual field and then brings it slowly toward the mid-line. The observer compares the position at which he first sights his finger with that at which it is first seen by the patient. The procedure is repeated from various directions, above, below and from either side.

The optic tract and primary optic centers

The visual pathway from the chiasma to the primary optic center consists of compact bundles of fibers—the *optic tract*. In the optic tract bundles of nasal and temporal fibers intermingle, but those from the upper quadrants of the peripheral retina tend to lie ventro-laterally, those from the lower quadrants ventro-medially. The macular fibers lie dorso-laterally. The optic tract passes backwards and outwards between the tuber cinereum and the anterior perforated substance to the cerebral peduncle around which it turns as a flattened band to reach the *external (lateral) geniculate body*.³ In this, the *primary visual center*, the great majority of the optic fibers end. A smaller number are continued to the *superior colliculus* (superior corpus quadrigeminum) but

none of these are of macular origin. The superior colliculus serves as a center for light reflexes and for the correlation of impulses from the retina with movements of the skeletal muscles, but apparently not for sight. The pulvinar of the optic thalamus has been generally looked upon as a relay station for visual impulses, but the researches of Brouwer and Zeeman lend no support to this belief; in monkeys, no degenerated fibers were observed to end in the pulvinar after excision of the eyeball. It has also been stated by Henschen that a lesion of the pulvinar in man does not cause hemianopia, whereas disease involving the external geniculate body but which spares the pulvinar produces complete hemianopia. The pulvinar may, however, be concerned with eye movements and visual judgments, e.g., the recognition of depth (stereoscopic function) and distance. Its connection with the angular gyrus which is a center for eye movements suggests that it serves these functions, but in order to do so it would require to be in communication also with the visual area of the cortex or with the external geniculate body. Such connections have not been demonstrated.

The *optic radiation (geniculocalcarine pathway)*. The visual fibers after leaving the external geniculate body pass through the posterior extremity of the internal capsule, and curving forward and outward into the temporal lobe sweep backward in relation to the outer aspect of the posterior horn of the lateral ventricle to reach the *area striata* (area 17) of the occipital cortex (pp. 886 and 896). The optic radiation also contains descending fibers which end in the superior colliculus and the external geniculate body.

The *visual cortex*. This comprises that part of the cortex referred to above as the area striata, which forms the walls and lips of the calcarine fissure on the mesial aspect of the occipital lobe. The different retinal areas in their projections upon the cortex show definite localization. The homonymous halves of the peripheral retinas are represented in the anterior three-fourths of the visual area, the upper quadrants in the upper wall and lip, the lower quadrants in the lower wall and lip. In other words, the nasal half of the right retina and the temporal half of the left are projected on to the left occipital cortex—the projection of the upper quadrant in each case lying above that of the lower quadrant. Similarly, the nasal half of the left retina and the temporal half of the right are projected on to the right striate area. The macular representation is less extensive. It occupies the posterior part of the striate area

³ The projection of the retina upon the external geniculate body has been studied by Brouwer and Zeeman in monkeys. These observers produced localized lesions in the retina and examined the geniculate body histologically after time had been allowed for degeneration of the optic fibers. It was found that the retinas were not projected diffusely throughout the primary optic center, but showed localization of their different regions to definite sections. Thus the upper parts of the peripheral retinas, both nasal and temporal, of the two eyes were projected to the medial parts of the geniculate body. The lower parts of the retinas were represented in the lateral part (fig. 464, E). Dorsal to these regions and wedged between them was an extensive area wherein the macular fibers terminated. Binocular and monocular types of vision have separate representations. In the monkey the area which receives fibers from only one eye is very small, occupying a small rim on the ventral aspect of the primary center. In the rabbit, on the other hand, the monocular projection occupies almost the entire geniculate body, binocular vision being represented by a narrow area on the medial aspect of the geniculate body.

reaching backwards to the occipital pole, but it also spreads forwards to overlap the projection area of the peripheral retina (fig. 466). As in the case of the peripheral retina, the upper and lower parts of the macula are projected to the upper and lower halves, respectively, of the striate area. The cortical projection of the macula is possibly bilateral,⁴ i.e., represented in its entirety in both hemispheres, since the retention of macular vision in both eyes after destruction of the pole of one occipital lobe has been reported (Brouwer).

fibers in the outer angle of the chiasma, as by an aneurysmal dilatation of the internal carotid artery, may produce blindness in the temporal part of the retina of the same side. If these fibers on both sides are affected, the sight in the temporal half of each retina may be lost (*bi-nasal hemianopia*). According to Cushing a dilated third ventricle may, by pressing from above, force the angles of the chiasma against sclerosed internal carotid arteries and so produce a bi-nasal hemianopia. (b) Pituitary tumors, owing to the

FIG. 466. Diagram showing the projection of the retina on the calcarine cortex (from Holmes). Right half figure is temporal half of right visual field (p. 1637).

The effects of lesions at different levels of the visual pathway (see also p. 1013)

(1) A destructive lesion of one optic nerve will result in total blindness of the corresponding eye (fig. 467). Increased intracranial pressure may cause atrophy of the optic nerves and a gradual concentric reduction of the visual fields of both eyes.

(2) A lesion involving the chiasma will result in visual defects whose nature will depend upon the fibers destroyed. (a) Pressure upon the uncrossed

position, are likely to involve the nasal fibers at the point of their crossing and thus cause *bi-temporal hemianopia*. Since the nasal fibers from the lower retinal quadrants lie ventral to those from the upper, the lower are likely to be involved first in pituitary tumors; *superior temporal quadrant hemianopia* will result. Lesions (e.g., tumor pressing from above tend first to cause defects in the lower temporal quadrants of the visual field. Dilatation of the third ventricle or a tumor of the pituitary stalk may produce such an effect.

(3) Lesions of the optic tract, of the primary visual center or of the optic radiation will result in *homonymous hemianopia*. The right halves

⁴ For views on this question see Penfield and associates, *Arch. Neur. Psych.*, 1935, 33, 816, and Maison and associates, *ibid.*, 1938, 40, 981.

the two eyes (left halves of the visual fields) being effected in right-sided lesions and the left halves in left-sided lesions. An abscess or tumor of the temporal lobe may, by involving the optic tract or optic radiation, cause a homonymous hemianopia. When the optic radiation is pressed upon by a

(4) *Lesions of the occipital cortex.* A lesion involving the area striata of one hemisphere or the optic radiation before their termination therein results in an homonymous hemianopia, right or left, depending upon the side of the brain affected. Quadrantic homonymous hemianopia will result when the lesion is restricted to the upper or lower part of the striate area. Owing to the large cortical area representing the macular region, or perhaps to the fact that the macula is bilaterally represented, extensive occipital lesions or excision of a large part of this area often leave acute (central) vision intact, the blindness then involving only the peripheral half of each retina.

PUPILLARY REFLEXES

Reflex changes in the size of the pupil occur under the following conditions: (a) Constriction or dilatation occurs in response to changes in light intensity (light reflex). When light is thrown into the normal eye the pupil of that eye constricts promptly; this is the *direct pupillary reaction*. The pupil of the opposite eye, though shaded, also narrows; this, the *indirect or consensual pupillary reaction*, is dependent upon fibers which cross to the pupillary-constrictor center of the opposite side. (b) Constriction occurs as a part of the mechanism of accommodation to near vision (pupillary reaction of accommodation). With it are associated convergence of the eyes and accommodation of the lens. These three associated reactions are appropriately grouped under the term *near reflex* or *accommodation reflex*. (c) Dilatation follows stimulation of the skin of the neck (ciliospinal reflex). (d) Dilatation may occur during certain emotional states (e.g., fear), as a result of acute pain or a sudden sound. The pupil is extremely sensitive to the latter type of stimulus, responding by dilatation to sounds of different pitches at the lowest intensities which can be heard. (e) Finally, stimulation of labyrinthine receptors causes changes in the diameter of the pupil (p. 844). For example, rapid rotation of the body around its long axis causes dilatation of the pupil and rhythmical changes in its diameter (*hippus*).

THE PUPILLARY MECHANISM

The iris is the most anterior part of the vascular tunic of the eye. It is a thin contractile disc perforated a little to the nasal side of its center by the pupil. The pupillary margin rests upon the anterior surface of the lens. The space between the lens and the cornea is divided by the iris into a larger *anterior* and smaller

FIG. 467. Diagram to show the effects upon vision and pupillary reactions resulting from interruption of retinal impulses at various levels. 1, Optic nerve; blindness of corresponding eye, direct reaction of this eye and consensual reaction of sound eye lost. Consensual reaction of blind eye and direct reaction of sound eye retained. Near reflex unaffected. 2, Chiasma; bitemporal hemianopia. Wernicke's pupillary reaction. 3, Optic tract; homonymous hemianopia (blindness in nasal half of right retina and temporal half of left). Wernicke's pupillary reaction. 4, Optic radiation; homonymous hemianopia, light and near reflexes retained. 5, At synapses in the oculomotor nucleus. Light reflex lost, near reflex retained (Argyll-Robertson pupil, see also p. 1014). The lesion is usually bilateral (as in tabes, disseminated sclerosis, etc.); the afferent pupillary pathways are probably involved at their decussation in the midbrain.

temporal lobe lesion the hemianopia is very often complete, i.e., quadrantic. The ventral fibers of the radiation are likely to be implicated by a tumor in the lower part of the lobe, and a superior quadrantic hemianopia result. Injury to the nasal fibers tends to cause a defect confined at first to the lower homonymous quarters of the visual fields.

posterior chamber, the two chambers communicating through the pupil. The periphery (root) of the iris is attached to the anterior surface of the ciliary body and is continuous through the pectinate ligament (p. 1003). with the posterior elastic lamina of the cornea. The following five layers from before backwards compose the structure of the iris, (a) the anterior epithelium, (b) the anterior limiting membrane, (c) the stroma, (d) the posterior membrane and (e) the posterior epithelium. The *anterior epithelium* consists of a single layer of flat endothelial-like cells. Near the pupillary margin of the iris there are many small pits—the *crypts of Fuchs*—over which the epithelium is absent. The stroma is composed of loose connective tissue. It transmits the vessels and nerves and holds numerous branched cells which in dark eyes contain pigment granules. The iris contains two involuntary muscles—the sphincter pupillae and the dilator pupillae. The *sphincter pupillae* is embedded in the stroma and comprises a band of circular fibers about 1 mm. broad surrounding the pupil. When these fibers contract the pupil is constricted. The *dilator pupillae* constitutes the fourth layer of the iris, i.e., the posterior membrane, mentioned above. It consists of a thin layer of smooth muscle fibers which converge towards the pupillary margin where they blend with the fibers of the sphincter. At the root of the iris the dilator fibers pass into the ciliary body from which they take origin; when they contract they draw upon the pupillary margin and thus dilate the pupil. The *posterior epithelium* comprises two layers of deeply pigmented cubical cells; it is the continuation anteriorly of the pars ciliaris retinae (p. 993). The arteries of the iris form two vascular circles, one near the pupillary margin—the *circulus arteriosus minor*, the other near the root of the iris—the *circulus arteriosus major*. The two circles are connected by vessels which, arising from the larger circle, converge towards the pupillary margin where they form the smaller circle.

Blue or gray eyes owe their appearance to the pigment in the posterior epithelial layer as seen through the unpigmented stroma and other layers of the iris. The pigment cells of the stroma are responsible for the color of dark eyes, the shade varying with the quantity of pigment present. In the white races nearly all new-born babies have blue eyes because pigment does not develop in the stroma until some weeks after birth. But negro babies and others belonging to the dark races have brown eyes, the stroma pigment being well developed at birth.

Pupillo-constrictor pathways

It is generally believed that the receptors (cones but not the rods) of the light reflex are the same as those mediating visual sensations. It is likely that the pupil is under the control of nerve fibers activated by both rods and cones. Wagman and his associates have made the interesting observa-

tion that in dim light the curve of pupillary size at different intensities of a monochromatic light agrees closely with the visibility curve of the dark adapted human eye. The central connections of the afferent fibers of the pupillary mechanism are different from those of the visual fibers. They part company from the latter at the level of the primary visual center (lateral geniculate body). They do not traverse the latter but are continued through the brachium of the superior colliculus to the oculomotor nucleus on both sides of the brain. The superior colliculus itself is not interposed in their path, for Ranson and Magoun did not observe pupillary constriction when this part was stimulated. The partial decussation of the afferent fibers, occurs, Ranson and Magoun believe, in the posterior commissure. An earlier crossing of some fibers occurs also in the optic chiasma. Though under ordinary circumstances reduction in the tone of the pupillo-dilator center occurs reciprocally with activation of the pupillo-constrictor center, the light reflex can be carried out through the latter alone. The reflex is therefore retained after section of the cervical sympathetic (which conveys the dilator fibers). Since the afferent fibers mediating the light reflex separate from the visual pathway at the level of the lateral geniculate body, lesions of the optic pathway beyond this point do not interfere with the light reflex.

The *efferent* pupillo-constrictor pathway is constituted of parasympathetic fibers which arise in the oculomotor nucleus (probably the Edinger-Westphal nucleus) and are conveyed to the iris (sphincter pupillae) via the third nerve, ciliary ganglion and short ciliary nerves (fig. 468). The *near reflex* is dependent upon cortical centers. Impulses pass by association fibers from the occipital to the frontal cortex and thence via the internal capsule to the nucleus of the 3rd nerve. Peripheral to this the efferent pathway is the same as that for the light reflex. The afferent pathway is via the visual fibers i.e., external geniculate body and optic radiation, not through the superior colliculus. The reflex is bilateral, i.e., it occurs in both eyes when one is covered and the other directed to a near object.

DILATOR PATHWAYS. The dilator muscle receives sympathetic fibers which arise from the 8th cervical and the 1st and 2nd thoracic segments of the spinal cord and pass via the cervical sympathetic to the superior cervical ganglion. From here postganglionic fibers are conveyed along the

internal carotid artery into the cranial cavity. Entering the trunk of the nasociliary branch of the first division of the fifth nerve, they are transmitted to the iris in the long ciliary nerves. Some fibers also pass without interruption through the ciliary ganglion into the short ciliary nerves. These fibers supply in addition the smooth muscle of the orbit which lies in relation to the capsule of Tenon (fascia bulbi) and in the "check ligaments" of the ocular muscles. The smooth muscle forming the deep layer of the levator palpebrae superioris also receives innervation from the sympathetic. A higher pupillo-dilator center is situated in the hypothalamus (p. 883). This

When the sympathetic fibers are paralyzed the pupil is narrowed as a result of the unbalanced action of the constrictor fibers, and the dilatation of the pupil which normally follows the application of a stimulus, such as a scratch or pinch, to the skin of the neck (ciliospinal reflex) fails to occur. The pupil, however, still reacts to light. Drooping of the upper lid (ptosis) will result from paralysis of the smooth muscle of the levator palpebrae superioris and there may be recession of the eyeball (enophthalmos) from paralysis of the unstriated muscle of the orbit (see p. 951).

An investigation of the pupillary reactions may give valuable information concerning the site of a

FIG. 468. Diagram to illustrate pupillary reflexes. Interrupted lines indicate the dilator reflex, plain lines the constrictor reflex and visual pathway to the level of the lateral geniculate body; hatched lines show path of near reflex from lateral geniculate body to the cortex and nucleus of the 3rd nerve.

center in turn is probably connected with the cortex of the frontal lobe. It sends fibers through the midbrain which, according to the researches of Beattie, pass ventrally to the posterior commissure to enter the superior colliculus, thus coming into close relationship with the afferent pupillo-constrictor fibers. The pathway is continued downwards through the reticular formation of the pons and medulla to the spinal center. The pupillo-dilator reflex involves reciprocal inhibition of pupillo-constrictor tone. This is the paramount factor in the dilator reflex, for after section of the sympathetic pupillary fibers, the pupil dilates in the dark, or in response to a painful stimulus or emotional excitement, in an almost normal fashion.

lesion in the brain (see fig. 467, p. 1011). (a) A lesion destroying one optic nerve, since it interrupts the afferent pathway but leaves the efferent intact, abolishes the direct but not the indirect (consensual) reaction on the blind side. The direct reaction on the sound side is, of course, retained but the indirect is lost. That is to say, a light thrown into the sound eye causes a response in this eye as well as in the blind eye, but a light thrown into the blind eye is without effect upon either eye. The near (accommodation) reflex is not abolished. Blindness due to destruction of both optic nerves results in the loss of the reflexes for light as well as of those for accommodation. (b) Hemianopia due to a lesion of the chiasma, or

of the optic tract, results in the loss of both the direct and indirect reactions to light thrown upon the blind half of either retina. Light falling upon the sound halves of the retinas causes the normal response. This is known as *Wernicke's hemianopic pupillary reaction*.⁵ (c) Loss of the light reflex (both direct and indirect reactions) with retention or even exaggeration of the accommodation-convergence reflex is known as the *Argyll-Robertson pupil*. The pupil is also, as a rule, smaller than normal (myosis) and does not dilate to a painful stimulus nor fully to atropinization; the vestibular reflex is frequently absent as well. The abnormal pupillary responses occur quite apart from any defect of vision. Though usually bilateral the Argyll-Robertson pupil is sometimes confined to one side. It is most commonly seen in syphilitic degeneration of the central nervous system (e.g., tabes), but occurs in other conditions as well. The site of the lesion responsible for the Argyll-Robertson pupil is not known precisely. Merritt and Moore give evidence for placing it in the region of the posterior commissure where presumably, the neighboring dilator pathway is also interrupted. Scala and Spiegel believe from the results of their experiments that the disease involves the synapses between the afferent and efferent neurons of the light reflex, that is, in the oculomotor nucleus itself. (d) Destruction of the oculomotor nucleus or of the efferent pathway abolishes all light and accommodation reactions on the same side. The direct and indirect reactions are retained on the contralateral side. (e) Lesions involving the visual pathway after the separation of the visual and pupillary fibers, e.g., geniculate body, optic radiations or occipital cortex, leave the light reflex unaffected. (f) A bilateral lesion implicating the pathway from the cortex to the center for accommodation in the oculo-motor nucleus will cause a loss of the near reflex and leave the light reflexes intact. This is the converse of the Argyll-Robertson pupil.

The effects of drugs upon the pupil and ciliary muscle

Dilatation of the pupil is spoken of as *mydriasis*; constriction as *miosis*. Drugs which cause pupillary dilatation are therefore called *mydriatics*; those which cause constriction, *miotics*. Paralysis of the ciliary muscles is known as *cycloplegia*; drugs which cause this effect are called *cycloplegics*.

⁵ Owing to the difficulty of confining a beam of light to the blind half of the retina it is not an easy matter to demonstrate this reaction.

Mydriasis is caused by drugs which:

- (a) Paralyze the peripheral constrictor (parasympathetic) mechanism, such as atropine, or homatropine. Atropine is also cycloplegic, homatropine much less so.
- (b) Stimulate the dilator (sympathetic) mechanism, e.g., adrenaline, cocaine. These drugs have no effect upon accommodation.

Miosis is caused by drugs which:

- (a) Stimulate the peripheral constrictor mechanism, e.g., pilocarpine, physostigmine, muscarine. These drugs also cause spasm of the ciliary muscles.
- (b) Diminish the inhibition of the constrictor center, e.g., morphine. The action of this drug upon the pupil depends largely upon the intensity of the illumination. It appears, therefore, to exert its effect, mainly, by increasing the sensitivity of the light reflex.
- (c) Stimulate the constrictor center, e.g., picrotoxin.

Corresponding retinal points

When the gaze is directed to an object, an image is formed by each eye and impulses are conveyed to both sides of the brain, yet perfect fusion of the two images occurs in consciousness and only one image is seen. This characteristic of *binocular vision* is explained upon the theory of *corresponding retinal points*. The corresponding points in the retinas (foveas) which when stimulated simultaneously cause a single visual sensation, lie in the nasal half of one retina and the temporal half of the other. When the eyes are converged, the retinas are turned so that the images fall upon these corresponding parts. If, as a result of unequal action of the ocular muscles, this cannot be brought about, the separate images are not fused in consciousness and an object appears double. This abnormality of vision is known as *diplopia*.

The horopter. When the eyes are fixed upon any point in space, a number of other points can be located by calculation which are projected upon corresponding points of the two retinas (foveas). A line joining such points forms a circle called the *horopter* which passes through the fixation point and the nodal points of the eyes. The horopter will vary of course with the point of fixation of the eyes and does not exist unless the eye acts symmetrically (See Fig. 469). Points in the visual field lying outside the horopter do not fall on the corresponding points in the two retinas (peripheral retinas) and, as a consequence, actually cause a double impression. But this *physiological diplopia* as it is called does not thrust itself upon consciousness; it is suppressed or ignored and therefore does not cause confusion. Yet one can easily

demonstrate for himself that it exists. For example, when the eyes are fixated upon a near object, such as a pencil tip held close to the face, a more distant object may, through a conscious effort, be observed in duplicate.

STEREOSCOPIC VISION (GR. STEREOS, SOLID SKOPEO, 1 VIEW)

Our visual judgment of solidity, that is, our recognition that the object has depth as well as height and width, is due largely to the fact that corresponding points in the two retinas receive slightly dissimilar images of any given object. If the reader will look at some object in front of him, first closing one eye and then the other, he will find that the view seen by the right eye is slightly different from that seen by the left. The right eye is able to see more of the right side of the object, the left eye more of the left side. The two slightly disparate images are fused in the brain, yet the composite image has hidden within it something of each separate one; upon this the stereoscopic effect depends. The fusion of the dissimilar images by the brain, and the impression of depth and solidity produced thereby, lies in a field of psychology of which little is known.

The instrument known as a stereoscope produces an illusion of solidity by making use of the principle of simultaneous stimulation of the retinas by dissimilar images. A photograph taken with an ordinary camera appears flat because identical images are formed upon the retinas. A stereoscopic photograph, on the other hand, is taken by a camera provided with two lenses which are set, like the eyes, a short distance apart. Thus two slightly dissimilar views are taken which, when looked at through the stereoscope, are projected by means of prisms, one to each eye, so as to fall on corresponding retinal points. Steroscopic perception cannot, however, be explained entirely upon the basis of dissimilar retinal images, for though the discrimination of depth (or distance) is much more acute in binocular vision it is not abolished when one eye is closed. For example, when two objects are placed one in front of the other and viewed binocularly from a distance of about 6 meters the least distance between them which can be perceived by the average normal eyes is around 20 mm. When one eye is covered the least perceptible difference is increased to 120 mm. The other factors concerned in depth perception are as follows.

(1) *The apparent size of various objects in our field of vision.* We know from experience the approximate dimensions of the objects which we see, but the image which an object casts upon the fovea diminishes as its distance increases (p. 961). For example, a church steeple at a distance casts an image upon the retina no larger, perhaps smaller, than would a pencil held a few inches from the eyes. We know the relative sizes of the two objects, and therefore infer that the steeple must be far away and the pencil near.

(2) *The apparent change in color of an object with distance.* The atmosphere is not perfectly transparent or equally so for all wave lengths. Tree-clad hills, which we know to be green, appear bluish in the distance; the colors of many other objects appear to fade with distance, their detail and outline being dimmed by haze.

(3) *The blocking out of parts of a distant view by objects between it and the eyes* gives a sensation of depth.

FIG. 469. The horopter (Müller). F is the fixation point. The images of A, F, and B fall upon the retinae at corresponding points as aa' , ff' , and bb' . The projection of all such corresponding points lies upon the circumference of the dotted circle. It is obvious that there is a different horopter for each position of F. (After Duke-Elder, *Text Book of Ophthalmology*.)

(4) *Mathematical perspective.* Straight lines running into the distance which are actually parallel (or objects along imaginary straight lines) are convergent in the retinal image. When we look down a railway track, for example, the rails appear to converge towards some point beyond the horizon. This arrangement of lines in the retinal image we have come to associate with distance. The artist draws objects along imaginary lines which run towards a point in the background of his picture.

(5) *Parallax.* When one moves in any direction, near objects appear to move in the opposite direction, those in the background in the same direction as ourselves. This apparent movement of near objects in relation to ones farther away is called parallax; it is also produced by a movement of the head or eyes, even though the body remains stationary. Now, involuntary movements of the eyes are continually taking place with the production of parallax; this is believed to be an important but not an essential factor in giving us a sense of depth. That it is not an essential factor in depth

perception was proved by Dove (1841) who found that objects illuminated by an electric spark were seen in three dimensions; the stereoscopic effect, as was shown later by Volkmann, is experienced, though the duration of the flash is only 0.000,001 second.

(6) *The distribution of light and shade over the surface of an object and the shadow which it casts upon its surroundings* is also an important factor in the production of the stereoscopic effect.

Normally, the images formed by the two eyes are very nearly equal in size, varying by less than one per cent. When they differ in size to a degree which prevents perfect fusion with a consequent impairment of binocular vision the condition is spoken of as *aniseikonia*. Little interference with binocular vision results unless the inequality of the images is more than four or five per cent. Aniseikonia may be a factor, according to Bielschowsky, in the production of strabismus.

OCULAR MOVEMENTS

The innervation of the ocular muscles

The nerves supplying the extrinsic muscles of the eye are the 3rd (oculomotor), 4th (trochlear) and the 6th (abducent). The oculomotor nerve supplies all the extrinsic muscles of the eyeball except the superior oblique and the external rectus. It also supplies the striated portion of the levator palpebrae superioris and conveys parasympathetic fibers to the sphincter pupillae (p. 1012) and ciliary muscle. The deep smooth muscle component of the elevator of the lid is innervated by the sympathetic (p. 1013).

THE NUCLEUS OF THE 3RD NERVE is situated in the floor of the Sylvian (cerebral) aqueduct and subjacent to the superior colliculus. It is in close relation to the medial longitudinal fasciculus (p. 857). It is composed of a group of five smaller nuclei (fig. 470).

(a) The *central nucleus* (Perlia's nucleus) fuses with its fellow of the opposite side to form a single gray mass in the mid-line. It is probably the center for convergence of the eyes (internal recti). (b) The *caudal central nucleus* lies in line with and behind the former. It also fuses with its fellow of the opposite side. Functionally it is considered a part of the central nucleus and is shown by Brouwer and others as actually continuous with the latter. (c) The *dorsi-lateral nucleus*. It and the next two nuclei are paired. The dorsi-lateral nucleus is probably the center for upward movements of the eyes (superior rectus and inferior oblique muscles). The *striped muscle* of the levator palpebrae superioris also, it is believed, receives its innervation from this nucleus. (d) The *ventrimedial nucleus*, lying medial, ventral and caudad to the preceding is thought to be concerned with downward movements (inferior rectus). (e) The *Edinger-Westphal nucleus* lies on each side dorsal and lateral to the central nucleus.

It is believed to supply fibers to the sphincter pupillae and ciliary muscle.

The axons arising from these cell groups pass for most part into the nerve of the same side. A few fibers supplying the internal and inferior recti and inferior oblique muscles decussate with those of the opposite side.

The fibers after issuing from the oculomotor nucleus form a well-defined tract (tract of the oculomotor nerve) which runs downwards and forwards through the tegmentum, traversing the red nucleus and mesencephalic portion of the substantia nigra. They emerge from the medial aspect of the cerebral peduncle.

THE NUCLEUS OF THE TROCHLEAR NERVE lies on the floor of the cerebral aqueduct adjacent to the posterior end of the ventri-medial nucleus of the oculomotor nerve, and on a level with the inferior colliculus. It supplies the superior oblique, and, with the ventrimedial part of the oculomotor nucleus, forms a center for downward movements of the eye. The fibers arising from the trochlear nucleus differ from those of any other cranial nerve in that the great majority decussate with those of the opposite side. After leaving the nucleus the fibers curve dorsally around the central gray mass surrounding the aqueduct to reach the anterior medullary velum in which the decussation occurs. They emerge from the dorsal surface of the anterior medullary velum on one side of its frenulum and immediately behind the inferior colliculus.

THE ABDUCENT NUCLEUS furnishes fibers to the external rectus. It lies in the pons close to the median line and subjacent to the upper part of the floor of the 4th ventricle. Its fibers pass downwards and forwards through the pons to emerge without crossing at the latter's lower border. The fibers of the facial nerve loop around the abducent nucleus (p. 860).

The nuclei of the three ocular nerves receive fibers from: (a) the pyramidal tract of the opposite side, (b) the medial longitudinal fasciculus through which the three nuclei are connected with one another, with the vestibular nucleus, with the spinal cord and probably with the facial nucleus. It has been suggested that fibers from the oculomotor nucleus may enter the lateral nucleus and be then conveyed in the facial to the orbicularis oculi and the corrugator supercilii. The tectobulbar tract which relays to the three nuclei impulses entering the superior colliculus from the optic tract and the visual cortex.

The eyes are said to be in a *position of rest* in their *primary position* when their direction is maintained simply by the tone of the ocular muscles, that is, when the gaze is straight ahead and far away and not directed to any particular point in space. The visual axes are then parallel. When the eyes view some definite object they are turned by the contraction of the ocular muscles and converged so that the visual axes meet at the

erved object and an image of the object falls upon a corresponding point on each macula (p. 1014). The closer the object to the eye the greater the degree of convergence (p. 997). This movement of the eyes for the acute observation of an object is called *fixation*. The point where the visual axes meet is called the *fixation point* and the lines joining the latter to the fovea, i.e., the central axes, are sometimes called the *fixation lines*. The widest limits of vision in all directions within which eyes can fixate is called the *field of vision*. When surveyed by means of the perimeter it is found to be nearly circular with a diameter about 100° . Its boundaries therefore lie well within the limits of the binocular visual field (1006).

The eyeball is rotated in its socket (formed by the *orbita bulbi*) by the ocular muscles around one or other of three *primary axes* which intersect one another at right angles near the center of the globe. One axis is vertical, around it lateral movements (adduction and abduction) take place, i.e., in the horizontal plane. Another runs from before backwards and coincides with the visual axis; movements in the frontal plane (torsion or wheel movements) take place around it. The third is transverse, it is the axis of rotation for upward and downward movements, i.e., movements in the sagittal plane. Though the movements of the eyeball are essentially and for practical purposes rotary in character, a very slight translatory movement may take place as a result of movements of the lids and variations in the width of the palpebral fissure, closure and opening of the lids causing a displacement backward and outward, and forward and inward, respectively. A slight displacement at right angles to the rotary movement also takes place during contractions of the ocular muscles, the eyeball therefore executing what has been described by Berlin as a screw movement. For this reason the center of rotation of the eyeball is not an absolutely fixed point but varies slightly. For general purposes, however, it may be taken as the point of intersection of the primary axes. This point is on the visual axis about 13 mm. from the anterior surface of the cornea.

In table 79 the actions of the individual ocular muscles are given, but no normal movement is effected out by one of these muscles alone. Thus, when the eye is abducted, the external rectus and the two obliques act in unison to turn the eye inwards. The depressor and elevator components in the actions of the respective oblique muscles cancel one another. Similarly, adduction effected by contraction of the internal rectus is balanced by the superior and inferior recti. Again,

the depressor and elevating actions of the latter two muscles neutralize one another. In looking upwards the eye is elevated by the combined action of the superior rectus and the inferior oblique. In looking downwards the inferior rectus and the superior oblique act together, the subsidiary action of the inferior rectus in turning the eye inwards being offset by the opposite action of the superior oblique. This compound action of the ocular muscles makes for smooth and steady movement and rapid fixation of the eyeball. It will be seen from figure 471 that the obliques and the superior and inferior recti when contracting individually produce a rotary or wheel-like movement. When acting in pairs the rotary actions being in opposite

FIG. 470. A scheme of the various groups of cells which together constitute the nucleus of the oculomotor nerve. A, the dorsolateral nucleus; B, the ventrimedial nucleus; C, the central nucleus; D, the Edinger-Westphal nucleus; E, the caudal central nucleus; m, the third ventricle (from Gray, *Anatomy of the Human Body*, after le Gros Clark).

directions antagonize one another so that normally no such movement occurs. It has been stated by Hering that every central influence governing eye movements, excitatory or inhibitory, reaches both eyes equally (Hering's law) causing contraction or relaxation of associated muscle groups.

The actions of the eye muscles follow the principle of reciprocal innervation. Thus, when the eye is turned outwards the external rectus and the two obliques contract while their antagonists (inferior, external and superior recti) are inhibited. The two eyes act in unison, both turning in the same direction—*conjugate deviation*—and reciprocal innervation is extended to include muscle groups in the two eyes, thus indicating their control from a single center. Thus, stimulation of the posterior part of the 2nd frontal convolution causes conjugate deviation of the eyes to the opposite side. This involves contraction of the abductors and inhibi-

tion of the adductors of one eye and converse actions in the opposite eye (i.e., inhibition of the abductors accompanied by contraction of the adductors). Destruction of the cortical area results in the loss of the conjugate movement without paralysis of the individual

action of the affected muscle. (b) *Paralytic strabismus or squint*. When an effort is made to turn the eyes in the direction of the paralyzed muscle, the affected eye remains stationary or makes a smaller movement than does the sound eye. That is, it deviates in relation to the latter in a direction opposite to that of the normal action of the paralyzed muscle. The visual axes, therefore, do not bear their normal relationship to one another. This is called the *primary deviation*. If a screen is placed in front of the sound eye while an attempt is made to fixate the affected eye upon an object situated towards the side of the paralyzed muscle, the sound eye deviates in the direction of action of the latter. This *secondary deviation*, as it is termed, is greater than the primary deviation of the paralyzed eye. The greater deviation of the sound eye is attributed to the unusual effort exerted in the attempt to fixate the paralyzed eye, an unnecessarily strong motor discharge being transmitted simultaneously to the muscle of the sound eye which normally acts conjointly (conjugate deviation) with the paralyzed muscle.

(c) *Diplopia; false projection of the visual field*. It is as a result of weakness or paralysis of the muscles of

FIG. 471. Diagram to illustrate the actions of the ocular muscles. O.I., inferior oblique; RS, superior rectus; R ext, external rectus; R int, internal rectus; O.S., superior oblique; RI, inferior rectus (from Fuchs after Marquez).

TABLE 79

MUSCLE		MOVEMENT	INNERVATION	DIPLOPIA DUE TO OCULAR PARALYSIS POSITION OF FALSE IMAGE IN RELATION TO TRUE WHEN RIGHT EYE AFFECTED (APPLICABLE TO LEFT EYE IF RIGHT BE CHANGED TO LEFT AND VICE VERSA)
Rectus	Superior	Adductor and elevator	Oculomotor	Above, to left of and tilted away from true image (crossed diplopia)
	Inferior	Adductor and depressor	Oculomotor	Below, to left and tilted towards true image (crossed diplopia)
	Internal	Adductor	Oculomotor	Level with, parallel to and on the left of true image (crossed diplopia)
	External	Abductor	Abducens	Level with, parallel to and on the right of true image
Oblique	Inferior	Abductor and elevator	Oculomotor	Above, to right of and tilted away from true image
	Superior	Abductor and depressor	Trochlear	Below, to right of and tilted toward true image
Levator palp. sup.		Elevator of eyelid antagonizes the action of the palpebral part of the orbicularis oculi	Oculomotor	

muscles. The act of *convergence*, in which both eyes are adducted, is due to the conjoint contraction of the internal recti. The center for this movement is probably in the central nucleus of the oculomotor nerve. A higher center for the movement is also situated in the frontal cortex.

The effects upon the eye movements of paralysis or weakness (*paresis*) of the ocular muscles. (a) *Limitation of movement* of the eye in the direction of the normal

one eye, or of an imbalance from whatever cause occurs between the actions of the ocular muscles of the two eyes, the images do not fall upon corresponding retinal points and *diplopia* or *double vision* results. The image seen by the sound eye is called the *true image*, that seen by the affected eye is called the *false image*. The false image lies to one side, above or below the true image, depending upon the ocular muscle which is paralyzed. In the case of the oblique muscles and the superior

and inferior recti, the false image lies above or below the true image—a little to one or other side and tilted towards or away from it (see table 79, p. 1018). The false image is always displaced in the direction of the normal action of the paralyzed muscle. Thus, in paralysis of the right external rectus the right eye is not turned outwards when the subject attempts to look at an object towards his right side. The image of the object falls upon the temporal half of the left macula and is therefore projected into the nasal half of the visual field of that eye. But, in the affected eye the image falls upon the nasal half of the retina and is therefore projected into the temporal half of the right visual field. The image seen by the right eye (false image) therefore lies to the right of that seen by the left (true image). When the false image is on the same side of the true image as the affected eye the diplopia is said to be *simple* or *uncrossed*; if it lies on the opposite side of the true image the diplopia is said to be *crossed*.

If in a case of diplopia the sound eye is covered and the patient asked to turn his eyes, and to touch quickly an object placed to one side of his line of vision, but in the direction of the paralyzed muscle, he places his hand some distance from the object's true position. Normally, information concerning the positions of objects in space is to a large extent dependent upon

proprioceptor impulses arising in the ocular muscles. When, for example, we look at an object straight in front of us an image falls upon the macula of each retina. When we look at an object to one side the eyes are turned so that the images fall again upon precisely the same areas—the maculae. The actual position of the object—whether in front or to one side—is made known to us by afferent impulses set up in the muscles as they turn the eyes into position. Such impulses serve also as a basis for the nice correlation between visual sensations and various body movements. When, as a result of paralysis of certain muscles, the eye does not move with the sound eye, the impulses arising in the muscles of the latter convey the impression, nevertheless, that such a movement has taken place. Let us say the outward movement of the right eye is paralyzed and the left, sound eye, is covered; when the latter turns to the right the patient believes the paralyzed eye does so to the same degree. The image in this eye, which continues to look forward, falls upon the nasal side of the retina. Since earliest experiences have taught him that an image falling upon the nasal part of the retina when this eye is rotated outwards represents an object well over to the right, he falsely projects the image into this position, and makes the appropriate movement of the hand in an attempt to touch the object.

CHAPTER LXXVIII

THE EAR. ANATOMICAL OUTLINE. SOUND GENERAL PRINCIPLES

ANATOMICAL OUTLINE

In order that the reader may follow with the least effort the account of the physiological mechanisms of hearing, the anatomy of the auditory apparatus and especially those features having a direct bearing upon function will be briefly described. For a more detailed description reference should be made to any standard text on anatomy.

The external ear comprises the cutaneous and cartilaginous appendage known as the *auricle* or *pinna*, and the short passage—the *external auditory meatus* leading into and penetrating the temporal bone (fig. 472).

FIG. 472. Plan of the ear. (Redrawn and modified from Arnold.) 1, the auricle (or pinna); 2, external auditory canal (or meatus); 3, the tympanic membrane (sectioned); 4, the tympanic cavity (middle ear), the chain of ossicles lies just above the pointer; 5, Eustachian tube; 6, cochlea; 7, acoustic nerve, showing cochlear and vestibular divisions; 8, semicircular canals.

The external auditory meatus is an S shaped canal, being directed inwards, upwards and forwards, then, upwards and backwards and finally, forwards and slightly downwards to end blindly at the drum membrane. The inner 16 mm. or so of the canal (*pars ossea*) forms a tunnel in the temporal bone. The wall of the outer 8 millimeters of the meatus is composed of cartilage (*pars cartilaginea*); the entire canal, including its inner blind end formed by the drum membrane, is lined by skin.

The middle ear, *tympanic cavity* or *drum* is a chamber measuring about $15 \times 5 \times 2$ mm. and situated within the petrous bone. It is lined by mucous membrane. Except over the tympanic membrane and part of the inner wall, the epithelium is ciliated. The outer wall

of the tympanic cavity is formed mainly by the flexible *tympanic (drum) membrane*, while its inner wall which separates it from the internal ear is composed of bone except for the *oval* and *round windows* (*fenestra vestibuli* and *fenestra cochleae*). The inner wall presents a rounded eminence—the *promontory*—caused by the projection laterally of the basal turn of the cochlea. The oval window lies above the posterior part of the promontory. The round window which is closed by a delicate membrane is situated at the bottom of a deep hollow or niche lying just below this end of the promontory. The oval window lodges the footplate of the stapes. The tympanic cavity is filled with air which is maintained at atmospheric pressure by means of the *Eustachian tube (auditory tube)* which runs from the lower part of its anterior wall to the nasopharynx. The lower opening of this tube is closed at ordinary times but is dilated during swallowing by contraction of the *salpingopharyngeus* and *dilator tubae* muscles (see p. 1044).

The tympanic membrane is elliptical, measuring about 10 mm. in height and 9 mm. in width. It is placed obliquely, being directed from above downwards and forwards to form an angle of 55° with the anterior and inferior walls of the external auditory meatus. It possesses three layers, the outermost being of skin and the innermost of non-ciliated mucous membrane. The middle layer or *membrana propria* is composed of two sets of fibers—a radial and a circular—arranged somewhat like the threads of a spider's web. The drum membrane is drawn inwards at the center and along the attachment of the handle of the malleus; its lateral surface is therefore concave, its medial surface convex. The point of greatest concavity, which corresponds with the tip of the handle of the malleus, is called the *umbo* (fig. 473).

The drum membrane is observed during life by means of a light thrown into the meatus through an aural speculum. The healthy membrane viewed in this way is pearl gray in color, pinkish or faintly yellow. Above and anteriorly near its circumference the membrane presents a small white spot caused by the projection of the lateral process of the malleus; from this point a faint ridge corresponding with the handle of the malleus extends to the umbo. Two faint folds—the *anterior* and *posterior malleolar folds*—extend forward and backward, respectively, from the lateral process of the malleus, enclosing a small triangular area. The part of the tympanic membrane within this area is thin and lax; it is known as *Shrapnell's membrane* or the *pars flaccida*. The rest of the drum membrane is tight and

glistening (*pars tensa*). The lustre of the membrane gives rise to a bright triangular area, the "cone of light." This is situated with its apex at the umbo and its base directed downwards and forwards. For convenience in describing the position of a lesion of the drum membrane it is mapped out into quadrants by a line represented by the handle of the malleus and its continuation downwards and by another passing through the umbo at right angles to the first.

Three miniature bones—the *auditory ossicles*—jointed together stretch across the tympanic cavity from the drum membrane to the oval window (fig. 474). These are named, somewhat imaginatively from their shapes, the malleus (hammer), the incus (anvil) and the stapes (stirrup). The *malleus* (8–9 mm. long) consists of a handle (or manubrium) which is attached along the upper half of the vertical diameter of the tympanic membrane, a head (or capitellum) and two processes, a lateral and an anterior. The *incus* is shaped like a premolar tooth; the anterior surface of its body presents a saddle-shaped facet which articulates

attached to the malleus—the *anterior, superior and lateral ligaments of the malleus*; a fourth connects the short process of the incus to the posterior wall of the tympanum; the fifth is the annular ligament of the stapes just mentioned.

The tympanum contains two minute muscles—the *tensor tympani* and the *stapedius*. The former arises from the roof of the cartilaginous part of the Eustachian tube and from the adjacent part of the great wing of the sphenoid bone; its tendon turns laterally to be inserted into the medial edge and anterior surface of the handle of the malleus (fig. 474). When it contracts it pulls the handle of the malleus inwards, thereby preventing excessive displacement outwards of the tympanic membrane. The stapedius takes its origin from within an eminence (*eminencia pyramidalis*) on the posterior tympanic wall and passing forwards is inserted into the posterior surface of the neck of the stapes; its action pulls the head of the ossicle backwards, thus tilting the anterior edge of the base outwards, i.e., towards the tympanic cavity, and reducing the pressure

FIG. 473. Left tympanic membrane (as viewed from the external acoustic meatus). (From Cunningham's anatomy.)

with the posterior aspect of the head of the malleus. The lower part of the articular facet is hollowed out for the reception of the prominent inferior margin of the facet on the posterior surface of the head of the malleus—the so-called *spur* or *cog-tooth* of the malleus. The incus has a long and a short process; the former projects downwards and, turning inwards at the tip, connects through a ball and socket joint with the head of the stapes. The *stapes* shows a base (footplate of the stirrup) and two curved crura which join laterally to form an arch; a rounded eminence called the head arises from the center of the latter. The slight constriction between the head and the junction of the crura is called the neck. The head of the stapes, as just mentioned, articulates with the incus. The base fits into the oval window and is coated with cartilage which is connected around its circumference to the margins of the oval window by a ring of elastic fibers, known as the *annular ligament*.

The auditory ossicles are connected to the walls of the tympanum by five ligaments. Three of these are

upon the perilymph. These muscles are under reflex control, contracting to sound stimuli over the entire range of audible frequencies. The thresholds for these reflexes are lowest for tones of from 2000 to 4000 c.p.s. (rabbit). A sound in one ear causes increased tone of the tensor tympani of the opposite ear. This muscle also contracts during yawning. The tensor tympani is supplied by the fifth nerve, the stapedius by the seventh.

Two main views have been expressed concerning the functions of the intra-aural muscles. Some believe that they are *protective* in action, their contractions tending to reduce the amplitude of the vibrations of the tympanic membrane and ossicles particularly to low tones, thus protecting the delicate structures of the internal ear from injury. The other view, generally referred to as the *accommodative theory*, holds that the stapedius and tensor tympani act to "tune up" the transmitting mechanism of the middle ear and thus to increase its sensitivity to any given vibration frequency. It has been shown, however, by H. Wiggers in the

guinea pig that the transmissibility of low tones (below 1000 cycles) to the internal ear is *reduced* by contraction of the stapedius and tensor tympani; the transmission of medium tones (1300 to 1800 cycles) is slightly enhanced while that of high tones (over 2000 cycles) is unaffected. In the human subject the transmission of tones within the range of a conversational voice and of all other tones of low pitch is reduced. These observations indicate that the function of the intra-aural muscles is mainly protective; any direct effect upon

are at its apex or *cupula* which is directed forwards and laterally, the largest turns at the base which look backwards and inwards and forms part of the outer wall of the *internal auditory meatus*. A ledge of bone (*lamina spiralis ossea*) winding around the modiolus like the thread of a screw-nail divides the spiral canal incompletely into two parts. The partition is completed by a membranous structure—the *basilar membrane*—which extends from the tip of the lamina spiralis ossea to the outer wall of the canal (see fig. 475). A second membrane—*Reissner's membrane*—stretches from the upper surface of the bony lamina to a point a short distance above the outer attachment of the basilar

FIG. 474. The auditory ossicles. 1, left malleus viewed from outer side, c, head, a.i, articular surface for incus; ma, handle. 2, left incus, pr.br, short process; pr.l, long process which articulates with stapes; a.m. articular surface for malleus. 3, left stapes, h, head; b, base or "footplate"; 4, the middle ear viewed from the inner aspect and showing ossicles in position; d, drum membrane; i, incus; m, malleus; st, stapes; ch.ty, chorda tympani nerve; l.s., ligament of malleus; l.i, ligament of incus; t.t, tendon of tensor tympani muscle.

auditory acuity is limited to a small pitch range. However, their action in reducing the efficiency of the transmission system for low tones may indirectly, by diminishing the masking effect (p. 1031) of such tones, increase the acuity for higher frequencies.

The *internal ear* or *labyrinth*, situated within the temporal bone on the inner side of the middle ear, contains the auditory sense organs. The latter lie within a spiral canal called the *cochlea* (L. a *snail's shell*). The canal makes $2\frac{1}{2}$ turns round a central pillar of bone called the *modiolus*. The smallest turns of the cochlea

FIG. 475. Upper, a view of the osseous cochlea divided through the middle. 1, scala vestibuli; 2, scala tympani; 3, modiolus, showing tunnels transmitting branches of auditory nerve. Lower, enlarged sketch of one turn of the cochlea (redrawn after Quain) S.V, scala vestibuli; S.M, scala media (cochlear duct); S.T, scala tympani; a, Reissner's membrane; b, basilar membrane; c, organ of Corti; d, auditory nerve.

membrane. The original osseous canal is divided in this way into three spiral compartments or galleries. The gallery below the basilar membrane is called the *scala tympani*, the one above Reissner's membrane, the *scala vestibuli*, while the one enclosed between the two membranes is known as the *scala media*, the *cochlear duct* or the *membranous cochlea*. The membranous cochlea is filled with a fluid known as *endolymph*, while the osseous canals, i.e., the *scala vestibuli* and *scala tympani*, are filled with *perilymph*. The *scala vestibuli* and *scala tympani* communicate with one another at the cupula of the cochlea through a small aperture called the *helicotrema*. The *scala media* ends here as a closed sac, but its basal extremity communicates with the non-auditory labyrinth through the *canalis reuniens* or *duct of Hensen* (p. 836). The *perilymph* and *endo-*

lymph have different origins. The former is actually cerebrospinal fluid, the osseous canals communicating with the subarachnoid space through the *ductus perilymphaticus* which passes from the floor of the vestibule to the posterior fossa of the skull. The origin of the endolymph is unknown; it is possibly a secretion or transudate furnished by the stria vascularis. The scala vestibuli opens out near the central part of the labyrinth into an ovoid osseous chamber (6 x 4 x 4 mm.) called the *vestibule*. This chamber contains the utricle and saccule; the osseous semicircular canals open into its posterior part (p. 835). Its lateral wall separates it from the middle ear and contains the oval window.

The auditory receptors. The sensory cells, together with sustentacular elements constitute a structure known as the *spiral organ of Corti* (fig. 476). This lies within the scala media, occupying the inner half or so of the basilar membrane. It presents towards its inner part two rows of elongated epithelial elements of peculiar shape—the *inner* and *outer rods* (or *pillars*) of

cells. The *outer* hair cells are longer than the inner and more numerous (12,000); they are separated from the basilar membrane by cells arranged in several rows—the *cells of Deiters*—which send slender processes between the rows of the sensitive cells. That part of the organ of Corti lying on the outer side of Deiters' cells and the outermost row of hair cells is composed of several layers of columnar cells—the *supporting cells of Hensen*.

The *tectorial membrane* is a delicate, almost homogeneous structure, somewhat paddle-shaped in transverse sections of the scala media; it overlies the inner half or more of the spiral organ. Arising from a point near the base of the lamina spiralis ossea it ends laterally in an irregularly fringed or scalloped free margin. The hairs of the sensory cells of all four rows are embedded in its under surface.

The structure of the basilar membrane. The inner part (*zona arcuata*) of the basilar membrane where it supports the spiral organ is thin; its outer thicker part (*zona pectinata*) is covered by a single layer of columnar

FIG. 476. Section across the organ of Corti. (After Retzius.)

Corti—which stand with their expanded bases planted upon the basilar membrane. The bases of the rods of the two rows are separated by an interval, but above the membrane their bodies incline towards one another and, meeting at an angle, their extremities fit into one another in a manner much as one clasps a fist with the other hand. They form by this arrangement a triangular tunnel whose floor is covered by two nucleated scraps of protoplasm which actually are the undifferentiated parts of the cells from which the corresponding rods have developed. The arches of Corti increase progressively in height from the basal to the apical turns of the cochlea.

The *hair cells* are the essential sensory elements. They are seen as four rows of short columnar cells, one row lying on the inner side and three on the outer side of the corresponding rod. The *inner* hair cells number about 3500; their free ends are in line with the surfaces of the rods, but their bases extend only half way to the basilar membrane. The free surface of each hair cell of both inner and outer rows is surmounted by some twenty hair-like processes. One or two rows of cells support the bases and inner aspects of the inner hair

cells named the *cells of Claudius*. The substantia propria of both zones of the membrane show numerous fibers—the *auditory strings*—embedded in a homogeneous ground substance. The strings in the outer zone are straight and smooth and run for the most part transversely; those of the inner zone are thinner and arranged in the form of a net. The total number of fibers in the human cochlea is 24,000, according to the generally accepted estimate of Retzius. The basilar membrane when uncoiled shows a gradual taper; it measures about 30 mm. in length in man. It is about three times wider at its apical than at its basal end. The auditory strings vary in length in a corresponding manner, being from 65 μ to 160 μ long at the base and from 350 μ to 500 μ at the cupula. The outer end of the basilar membrane is attached to the wall of the cochlear canal throughout its entire length by a ligamentous band called the *external spiral ligament*. This appears in sections of the canal as a conical structure composed of radiating fibers; it is relatively thick and strong in the basal turns but becomes progressively narrower in the direction of the cupula where it dwindles to a delicate strand.

The external spiral ligament is covered by cubical epithelium. Situated between the epithelial cells and the underlying fibrous tissue are numerous small blood vessels and capillary loops which together form a structure named the *stria vascularis*. The tissue surrounding the vessels contains pigment of varying amount depending upon the species. The *stria vascularis* is thought by some to have a secretory function.

Innervation of the hair cells. The cochlear division of the auditory (acoustic) nerve emerges as a number of fine filaments from the base of the modiolus in the internal auditory meatus. These are the central

of the 8th nerve after issuing from the internal auditory meatus, crosses the posterior fossa of the skull in close association with the vestibular division (p. 836) and the facial nerve. Reaching the lower border of the pons the cochlear fibers divide into two groups. The fibers of one group end around cells in the *ventral cochlear nucleus* situated upon the ventral aspect of the restiform body (fig. 477), those of the other group around cells of the *dorsal nucleus (tuberculum acousticum)* lying upon the dorso-lateral aspect of the restiform body. Secondary auditory neurons are situated in both these nuclei. The fibers issuing from

FIG. 477. Diagram of the auditory pathway (in part after Gray)

processes of the bipolar cells of the *spiral ganglion of the cochlea* which lies in the *spiral canal of the modiolus*; the latter twists through the bone along a line nearly corresponding with the origin of the lamina spiralis ossea. The peripheral processes (axons) of the bipolar cells proceed outwards in fine canals in the spiral lamina to its outer edge. The nerve filaments terminate as fine arborizations, some around the bases of the inner hair cells, others after crossing Corti's tunnel around the bases of the outer hair cells.

The non-auditory part of the labyrinth is described in Chapter LXVI.

THE AUDITORY PATHWAY. The cochlear division

the ventral nucleus pass medially, forming the trapezoid body and, crossing with those of the opposite side, ascend in the *lateral lemniscus*. (Some fibers from the ventral nucleus give off collaterals to the nucleus of the trapezoid body and of the superior olive; from these nuclei tertiary neurons convey impulses through the medial longitudinal fasciculus to the nuclei of the oculomotor, trochlear, abducens and spinal accessory nerves.) Fibers arising from the cells of the dorsal nucleus pass around the dorsal aspect of the restiform body, and proceed medially in the floor of the 4th ventricle, where they appear as well defined white strands—the *striae acousticae* (or *striae medullares*). Reaching the mid-

line they cross to the opposite side, and ascend with those of the ventral nucleus in the lateral lemniscus. Some fibers of the dorsal nucleus end in the nucleus of the superior olive, and some from both the dorsal and ventral nuclei join the lateral fillet of the same side. The lateral lemniscus as just indicated is composed of the secondary neurons of the auditory pathway and ascends in the reticular formation of the pons, its fibers ending in (a) the *substantia nigra*, (b) the *inferior colliculus* (corpus quadrigeminum), and (c) the *internal (medial) geniculate body*. Just as the superior colliculus serves as a center for visual reflexes, so the inferior colliculus is a center for auditory reflexes. It is not concerned with auditory sensations. It is connected by descending tracts with the nuclei of the brain stem and spinal centers (tectospinal tract). The internal geniculate body is the subcortical or primary auditory center.

The auditory radiation. The tertiary auditory neurons arise in the internal geniculate body, ascend in the posterior limb of the internal capsule external to the fibers of the optic radiation, and end in the cortex of the superior temporal convolution (Heschl's gyrus).

FIG. 478. Showing how one prong of a tuning fork compresses and rarefies the air. The circles represent little portions of air, while the springs are intended to show the elasticity of air. (After Watson, *Sound*.)

SOUND, GENERAL PRINCIPLES

All sound arises as a series of vibrations. The sound is transmitted through an elastic medium (e.g., air) as a train of alternating variations in pressure. For example, when the prongs of a tuning-fork are struck they vibrate, moving rapidly to and fro with a pendular motion and producing alternate compressions and decompressions (rarefactions) of the air in contact with their flat surfaces. The train of pressure alterations thus set up are transmitted through the air in all directions; reaching the drum membrane, they force it into vibration (fig. 478). The pendular movement of the tuning-fork is termed a *simple harmonic motion*. This movement is imparted to the air particles in contact with the prongs of the fork and through these to contiguous particles and so on through the medium. Simple harmonic motion may be illustrated by a mechanical model. In figure 478 the particles of air (O) are represented as connected by springs. When the prong of the fork moves outwards the first spring is compressed and a movement thereby transmitted to the attached particle.

The movement of the particle compresses the second spring and through it the corresponding particle, and so on through the series. The springs are not compressed all at the same instant but in succession, the movement of each particle occurring a little time after that of the particle immediately preceding. When the prong swings in the opposite direction the springs are stretched, the particles moving in reverse order, the movement showing a similar lag from particle to particle. Thus, the particles oscillate in a regular to and fro manner. Simple harmonic motion is defined as the *projection of a circular movement upon the diameter of the circle*. For example, if while a body is moving with constant velocity in a circle one observes it from a distance with the eye in the plane of the circle, it appears to oscillate back and forth like a shuttle along a straight line, that is, along the diameter of the circle. In order to indicate the location of the oscillating particle on its linear path at any instant, another particle,

FIG. 479. Illustrating simple harmonic motion and circle of reference. (After Wilkinson and Gray.)

purely imaginary, is supposed to be traveling in a circle and always keeping vertically above the actual one. The orbit of this imaginary particle is called the *circle of reference* (see fig. 479). The distance which the particle travels from its equilibrium point (which is the center of its linear path), i.e., half a full excursion, will, of course, be proportional to the radius of the circle and gives the *amplitude* of the vibration. The position of the particle in the circle of reference is called the *phase* of its motion. A complete movement, i.e., from one phase to the next corresponding phase is termed a *cycle* or *double vibration* (d.v.) and the number of cycles per second (c.p.s.) is the *vibration frequency*. The distance from one particle to the next one in the same phase gives the wave length. The compression or stretching of a spring in the model corresponds to the movement of a particle of the medium in the same or in the opposite direction, respectively, to that in which the sound wave is moving; in their movement with the wave the air particles are closer together (compression), during the opposite movement they are further apart (rarefaction). Simple harmonic motion is

the commonest type of motion set up in air particles by vibrating bodies and *all musical tones are due to such motions or to a combination of them in different phases* (p. 1029).

Though, as stated above, sound is conducted as a series of compressions and expansions of the air, it is customary to represent it graphically as travelling like a series of water waves. But it must be pointed out that this is merely a useful convention derived from the fact that if we attach a writing point to a pendulum or tuning-fork executing simple harmonic motion, and have it inscribe its excursions upon a moving surface, a series of such waves will be drawn. Such a simple regular type of wave produced by a tuning-fork and shown in figure 479 is known as a sine wave, because when different points upon the wave are correlated with the positions of the moving particle on the circumference of the circle of reference, the ordinate at each point on the wave is proportional to the sine of the angle which the radius joining the particle on the circumference makes with the diameter of the circle. Simple or pure tones are all produced by waves of this type.

The *velocity of sound* varies with the elasticity of the medium and inversely with its density. Increased elasticity raises the velocity (the imaginary springs between the particles being stiffer respond more rapidly); greater density slows the rate of transmission owing to the greater inertia of the particles. The velocity of sound waves is about 1100 feet per second in air, 4,700 per second in water, 13,000 per second in wood and 16,500 in steel. The velocity of sound in a medium is obtained from the equation $v = \sqrt{E/d}$, in which E = elasticity and d = density. The wave length of a given tone is readily obtained by dividing its frequency of vibration (number of cycles per second) into the figure expressing its velocity. Thus the wave length of a sound transmitted through air and with a frequency of 550 cycles per second is $\left(\frac{1100}{550} = \right)$ 2 feet.

Sound waves undergo *absorption, reflection, refraction* and *diffraction* in a manner closely similar to that exhibited by light rays (Chapter LXXVI). For example, sound waves travelling in one medium upon striking another possessing a different density or elasticity are in part absorbed, in part reflected and in part transmitted, the proportions disposed of in each of these ways depending upon the differences between the properties of the two media. Sound waves falling upon a substance such as felt, absorbent cotton or porous fiber board are largely absorbed, whereas those striking water or a hard smooth surface such as glass, steel or a plastered wall are nearly all reflected. A suitably curved concave surface of some hard material is capable of converging the sound waves to form a sound "image." Echoes and reverberations are caused by sounds thrown back towards their source from reflecting surfaces, and whispering galleries in

many instances owe their properties to the architecture of the hall—the walls or ceiling acting as a convex "mirror" to concentrate the sound waves within a small area. Sound is diffracted to a much greater extent than is light, owing to the much greater length (1,000,000 times at least) of the waves of the former. For example, sounds coming through a small open window spread out and fill the whole room just as though the aperture were itself a source of sound.

RESONANCE, FREE AND FORCED VIBRATIONS

Some sounding bodies, such as the strings of a harp, vibrate freely at a certain frequency after the force which set them in motion ceases to act. They are said to be tuned to a certain pitch or frequency; this is called their *natural frequency*. When sound waves corresponding to the natural frequency of such a body fall upon it, it vibrates and gives out the same note as it would if it were actually struck. This phenomenon is known as *resonance* or *sympathetic vibration*. For example, should one raise the dampers of a piano by depressing the loud pedal and sing a note near by or sound one upon a violin or other instrument, the string of the piano vibrates which if actually struck would give the same note—it "sings" in unison with the original tone. Though a resonator gives the maximum response to a sound having the same frequency it also vibrates less strongly to other frequencies a little higher or lower than its own.

A body which possesses no natural frequency is called *aperiodic*. When such is made to vibrate or when one which possesses resonating properties is made to vibrate at a frequency other than its natural frequency, as when a tuning-fork is driven by an alternating electric current, the vibrations are said to be *forced*. In setting up forced vibrations a much greater amount of energy must be expended than in the production of sympathetic vibrations. A vibrating tuning-fork, for example, while it will readily set up vibrations in another fork of its own frequency some little distance away must, in order to cause a body such as a table top to vibrate, be brought into direct contact with it. Vibrations forced in this way stop when the motion which set them up ceases; this phenomenon is due to *damping*.

THE CHARACTERISTICS OF SOUND

Sounds may differ from one another in three particulars, namely, intensity, pitch and quality or timbre.

INTENSITY. Sound intensity and loudness are

not synonymous terms. The former is a purely physical value, whereas the latter refers to the auditory sensation. The sensitivity of the ear varies with pitch, therefore of two sounds having the same intensity but of different pitches, one may be much louder than the other. Intensity refers to the energy (or power) of the sound waves and is proportional to the square of the pressure variations—the amplitude—of the waves; it may be quite independent of the auditory sensation. For example, a tone of a certain high pitch while inaudible, however intense, to the human ear, may be audible to some animals. Sound intensity is therefore given in physical units, namely, the number of dynes (or microwatts) passing through an area of 1 sq. cm.¹ An absolute unit is less generally useful, however, than one which indicates *differences* of intensity. It is now customary to use a scale in which the intensity of a sound is expressed as the logarithm to the base 10 of the ratio of two intensities; this unit is called the *bel* (after Graham Bell, the inventor of the telephone). The number of bels by which one sound intensity exceeds the other is called the *intensity level*. For example, if the intensity of the sound is increased ten times, say from 10^{-10} to 10^{-9} microwatts per sq. cm. the intensity level is raised by 1 bel; a hundred-fold increase in intensity corresponds to a rise in the intensity level by 2 bels, of a thousand-fold by 3 bels and so on. The reference intensity, i.e., the standard with which a given intensity is compared, may be anything we choose, since the bel is a purely relative value. The otologist or physiologist takes as his reference, the intensity of the faintest audible sound in a perfectly quiet room. The sound at reference intensity must be of the same pitch as that of the sound with which it is compared. The following intensity values of a number of common sounds are given by Beatty. The sound of leaves rustling in a gentle breeze has an intensity 10 times that of the faintest audible sound, a whisper at a distance of four feet 100 times, sounds in a quiet street 1000 times, a conversational voice at twelve feet 100,000 times, a loud peal of thunder 10,000,000 times, and sounds at the limit which the ear can endure, 10,000,000,000,000 times. The corresponding intensity levels are 1, 2, 3, 5, 7 and 13 bels, respectively. For

¹ 1 dyne = force which, acting on a mass of 1 gram for 1 second, produces an acceleration of 1 cm. per sec.;
 1 erg = work done by 1 dyne acting through 1 cm.;
 1 watt = 10^7 ergs per sec.; a microwatt = $\frac{1}{1,000,000}$ watt.

physiological or clinical work the bel is inconveniently large. A unit of $\frac{1}{10}$ bel, called the *decibel* (abbrev. db.) is used.²

PITCH is that property of sound which enables one to place a tone at a definite level in the musical scale. It is dependent mainly, though not entirely, upon the vibration frequency, i.e., upon the

FIG. 480. Illustrating the effect of fatigue upon pitch. (a) The blackened area indicates the distribution of fatigue among nerve-endings due to a 800 ~ tone. Hence the sensation due to a 1200 ~ tone is modified as shown by the curve (b), namely, sharpening of pitch for tones of higher frequency and flattening for lower tones. (From Beatty after Békésy.)

number of cycles falling per second upon the ear. That this property is not entirely a question of vibration frequency is shown by the fact that two sounds of the same frequency but at different in-

² The *sensation level* is defined as the number of decibels that a sound is above the audible threshold of a sound of the same pitch. If the hearing is normal the sensation levels and intensity levels coincide, but are different if the threshold of hearing is raised. The *loudness level*. The intensity level and sensation level and their unit the decibel can only be used for expressing differences between sounds of the same frequency for, as we have seen, loudness varies with pitch. The loudness level is defined as the intensity level of a sound of 1000 c.p.s. At this frequency but at no other do the loudness level and the intensity level coincide. The loudness level of any other pitch is determined by sounding a 1000 cycle tone—the *reference tone*—and raising its intensity until the two sounds are of the same loudness. The number of decibels by which the reference tone exceeds its audible threshold when the two tones are matched gives the loudness level. The energy of a 1000 cycle tone at the threshold of normal hearing is 10^{-16} watts per sq. cm.; this is therefore the zero or reference intensity on the loudness scale. The unit of the loudness level is sometimes called the *phon*. When the sound whose loudness is being measured has a frequency of 1000 c.p.s., decibel and phon are interchangeable terms, but at all other frequencies the latter term is specifically applicable. For example, when a tone has a value of 1 phon, its loudness is 1 decibel above the reference intensity of a 1000 cycle tone, not above that of a tone of its own frequency.

tensity levels may be judged by the ear as differing slightly in pitch.³ When the intensity level of a tone is raised it tends to become "flat" though its frequency remains the same; the pitch may be lowered at very high levels of intensity by as much as half a tone. The alteration in pitch in such an instance is attributed to the greater degree of tension exerted upon the resonating fibers of the basilar membrane (p. 1040), by the louder tone and the rise, in consequence, of their natural frequency of vibration. For example, if fibers which resonate to C are made to vibrate strongly to a loud sound which would ordinarily give that pitch, their frequency rises while the frequency of fibers which ordinarily respond to B is increased to a corresponding extent; they now respond to the loud C. Impulses reaching the cerebral centers are interpreted as having been caused by a tone which under

FIG. 481. Shows the form assumed by a string vibrating as a whole and in two, three, and four equal parts, respectively.

usual circumstances would set the B fibers into vibration (see Resonance Theory p. 1040).

The pitch of a note of constant frequency may also change as a result of auditory fatigue (see fig. 480). When the ear is fatigued by a tone, let us say of 800 c.p.s.,⁴ the end organs which are accustomed to respond to this frequency fail to do so or do so inadequately, while those on either side are little affected. As a result, the point of maximal stimulation (p. 1041) undergoes an apparent shift in one or other direction. A tone of a frequency a little lower than 800 c.p.s. therefore is flattened, one a little higher in frequency is sharpened.

THE HARMONIC SERIES AND THE DIATONIC SCALE. A body which executes a simple harmonic or pendular motion (p. 1025), such as the prong of a tuning-fork

³ There is no relation between intensity and frequency. The vibrations of a tuning-fork, for example, become weaker and weaker, i.e., of smaller and smaller amplitude, after it is struck but their frequency remains unaltered.

⁴ c.p.s., as mentioned on (p. 1025), is the abbreviation for cycles per second. It has the same meaning as d.v. (double vibrations).

or a stretched string, vibrating as a whole emits a pure or simple tone and will inscribe a sine curve. Simple tones whose frequencies are such as to form a series in which the higher frequencies are simple multiples of the lowest constitute an *harmonic series*. The ratios of the frequencies are represented by the numbers 1, 2, 3, 4, 5, 6, etc. For example, the frequencies of a series of tuning-forks of which the first vibrates at 250 cycles per second, will be 250, 500, 750, 1000 cycles per second, and so on. Or again, when a string or wire stretched tightly between two fixed points is struck so that it vibrates *as a whole*, it gives out the lowest tone of which it is capable. This is called its *first harmonic* or *fundamental tone*. If a bridge is placed exactly beneath its center, either half of the wire vibrates at just double the previous frequency; if divided into thirds the frequency is trebled. Divisions into quarters, fifths, sixths, etc., give corresponding frequencies. A tone having a frequency double that of the fundamental is called the *second harmonic* or *overtone* or the *octave*.

FIG. 482. (a) Wave-form of pure tone of frequency f (solid curve) and of frequency $3f$ (dotted curve). (b) The compound wave.

These considerations lead us to the important *law of lengths*, which states that the number of vibrations per second of a stretched string is inversely proportional to its length. The *laws of diameters*, of *densities* and of *tension* may be summed up in the statement that the vibration frequency is inversely proportional to the diameter of the string and to the square root of its density, and is directly proportional to the weight by which it is stretched. The natural frequency of a stretched string is given by the formula $n = \frac{1}{2l} \sqrt{\frac{T}{m}}$, where n is the number of cycles per second, l the length of string in cm., T the tension in dynes and m the mass of string per cm. of length.

A string when plucked or set into rapid vibration in any way very rarely vibrates with one motion through its entire length; it also vibrates in sections or *loops* which vary in number depending upon the length, tension and mass of the string. The fixed points separating the vibrating sections are called *nodes* (fig. 481). If the string vibrates in halves it gives out not only its fundamental but its octave as well; if it vibrates in thirds the third harmonic is added, and so on. A column of air as in an organ pipe behaves in a somewhat similar manner, giving out a note composed of the

fundamental and a number of overtones. The different motions of the string or air column are imparted to the surrounding air with the production of waves, each of which is composed of the waves caused by the overtones superimposed upon the one due to the fundamental. The composite wave repeats itself at the frequency of the fundamental which therefore determines the pitch of the sound (see Complex Sounds below).

The *diatonic scale* comprises eight notes designated C D E F G A B C', including the fundamental and the octave. C is the fundamental or *unison* and C' the octave. Whatever the actual level at which the scale is pitched⁶ the ratios between the frequency of the fundamental and that of the other tones is constant. The seven notes D E F G A B C' can be produced by dividing a stretched string into 8/9, 4/5, 3/4, 2/3, 3/5 and 1/2 respectively. The frequency of each tone is the reciprocal of the corresponding fraction into which the string is divided, namely, 9/8, 5/4, 4/3, etc., etc. It follows that each tone in the scale also bears a definite ratio to the one below it. The frequency ratios are given below.

Note	C	D	E	F	G	A	B	C'
Ratio to C		9	5	4	3	5	15	
	1	8	4	3	2	3	8	2
Ratio to preceding note	9	10	16	9	10	9	16	
	8	9	15	8	9	8	15	

Two tones having a frequency ratio of $\frac{9}{8}$ or $\frac{10}{9}$ are said to differ in pitch by a whole tone. Those with ratios of $\frac{9}{8}$ are called *major tones* and those of $\frac{10}{9}$ *minor tones*. If the ratio is $\frac{16}{15}$ the difference in pitch is a *half tone* or *semitone*.

The intervals are named according to their positions in relation to the first note of the scale, as follows.

Ratio	Name of interval
1:1	the unison
1:2	the octave
2:3	the fifth
3:4	the fourth
4:5	the major third

In the so-called *tempered* diatonic scale, to which tuning-forks, the pianoforte and certain other musical instruments are tuned, the octave is divided into twelve equal intervals. Each note rises in the scale by a semitone having a frequency exactly 1.05946 times greater than the one below it (1.05946 is the 12th root of 2, the ratio of the octave).

QUALITY OR TIMBRE. That property of sound

⁶ By international agreement the frequency of middle of the piano has been set at 261 c.p.s.

by which one distinguishes between two tones of the same pitch and intensity, e.g., the note of a violin from a bugle note, is called *quality* or *timbre*. It is determined, by the wave form. Sounds can be classified into *noises* and *musical tones*. Noises are defined as sounds (usually disagreeable or at least undesirable) possessing no regular period or definite pitch.⁶ Musical tones are due to waves which are repeated in regular sequence; they may be simple or complex, harmonious or discordant. A simple tone such as that produced by a tuning-fork is usually agreeable but monotonous and uninteresting.

The sound wave of a complex tone is a composite one formed by at least one wave of higher frequency superimposed upon that of the fundamental or simple tone. To the higher frequencies, i.e., to the overtones or harmonics the particular quality of a given musical sound is due. The higher frequencies and the characteristic form of the wave for which they are responsible are produced within the wave length of the lowest or fundamental tone. Thus if the fundamental tone is 100 c.p.s. and waves of higher frequency—200 c.p.s., 300 c.p.s., etc.—are superimposed upon it, then the entire compound wave repeats itself 100 times per second; the pitch of the tone is determined by the latter frequency and its quality by the frequencies and volumes of the overtones (see fig. 482). The ear of the ordinary person cannot readily distinguish the separate overtones, but they are perceived by the trained ear of the musician. A complex sound can be analyzed into its components by means of a series of resonators; when the tone is produced in their vicinity only those resonators respond which have natural frequencies corresponding to the simple tone components. It was shown mathematically by Fourier that any regular periodic vibration can be resolved into two or more simple harmonic motions; the fundamental in all instances having the same frequency as that of the compound wave. This statement is referred to as Fourier's theorem.

The most harmonious sounds are complex tones, especially the combinations of such simple tones as the octaves C and C' (ratio 1 to 2), C and G (ratio 3 to 2) or C, E and G. Any tones whose frequencies are proportional to the simple numbers 1, 2, 3, 4, 5, 6 combine to produce an agreeable sound. Certain other combinations are discordant. According to Helmholtz's theory of harmony, the discordance is due to the production of beats (see p. 1031).

⁶ There are many discordant sounds possessing a regular period of vibration and a definite pitch which though technically classed as musical sounds would certainly be called noises by most persons.

CHAPTER LXXIX

AUDITORY SENSATIONS. THE MECHANISM OF HEARING. THE TELEPHONE AND RESONANCE THEORIES

THE THRESHOLD OF HEARING. The least perceptible sound causes a pressure variation at the ear of $\frac{1}{120000}$ bar¹ or a force of $\frac{1}{120000}$ dyne per square centimeter, or in energy units, about 10^{-9} to 16^{-9} microwatts per square centimeter. These almost incredibly low values are for a sound vibration of 2700 cycles per second but, as already stated, the level of the threshold of hearing is variable, depending upon the frequency of the vibrations. The ear is most sensitive to pitches ranging from 2000 c.p.s. to 5000 c.p.s., i.e., to the upper two octaves of the pianoforte. The maximum sensitivity is for tones of 2700 c.p.s. Below and above the range from 2000 c.p.s. to 5000 c.p.s. the threshold rises rather rapidly (see fig. 483). The lowest audible frequency is about 16 c.p.s., the highest between 20,000 and 30,000 c.p.s. At the upper and lower limits the intensity must be increased enormously above that required for a tone of 2700 c.p.s.; a sound of the lowest frequency in order to be heard must have a pressure of 100 bars and at 20,000 c.p.s. a pressure of 500 bars is required. In terms of energy, that required to make the highest frequency audible is nearly forty million million times greater than is necessary for a note of 2700 c.p.s.

The range of audible frequencies varies considerably between different species. The upper limit is highest in bats; sounds with frequencies far above the audible range of the human ear, namely 98,000 c.p.s. can be heard. It is by means of the high-pitched (supersonic) cries which they emit and the detection of the echo of such sounds from objects in their path during flight that the bat is guided and enabled to avoid collisions.

THE THRESHOLD OF FEELING. When the sound is very loud (at pressure variations above from 10 to 1000 bars, depending upon the frequency) it is

¹ The bar is a unit of pressure and amounts to about one millionth of an atmosphere or to a pressure of 1 dyne per sq. cm. At sea level a decrease in pressure of 1 bar results from a rise in height of 8 mm. At the threshold of audibility for frequencies to which the ear is most sensitive the pressure variation is equivalent to a rise of only about one four hundred millionth part of a millimeter. At such a minute pressure the linear displacement of the membrane has a value comparable with molecular dimensions, or about $1/100,000$ that of the wave-length of green light.

felt as well as heard. The threshold of feeling is highest for frequencies between 250 c.p.s. and 1000 c.p.s., and lowest for those near the limits of audibility. Thus a low rumbling sound is felt more than heard, and a high-pitched shrill note of high intensity arouses a decidedly unpleasant feeling within the ear. For most frequencies pressure variations above 600 bars cause pain and may result in damage to the auditory mechanism. The pain threshold is somewhat lower (between 100 and 200 bars) for frequencies between 2000 c.p.s. and 5000 c.p.s., i.e., for frequencies with the lowest audible thresholds.

The discrimination of differences in intensity and pitch. The least perceptible difference in intensity (ΔI) is dependent upon the original intensity level and also upon the pitch of the sound. For sounds of ordinary intensity and frequency, e.g., tones of musical instruments and of the human voice, a difference of about 25 per cent is just perceptible. This represents a rise or fall of one decibel. It is only within this range of audibility that the Weber-Fechner law (p. 965) is even approximately obeyed. The percentage increase in intensity that is just perceptible is less than 25 at higher and greater than 25 per cent at lower intensity levels. For loud sounds (60 db. or more) the least perceptible intensity difference remains fairly constant at between 5 and 10 per cent over a very wide range of frequencies, whereas a tone near the threshold of audibility and with a frequency of 60 cycles per second must be increased some 700 per cent before any difference is perceived. At low intensity levels $\frac{\Delta I}{I}$ varies with the frequency; it is smallest at 2050 c.p.s. but increases progressively as the pitch is raised or lowered above this frequency.

The sensitivity of the ear for pitch discrimination is greatest over the range from 500 to 4000 c.p.s. The least perceptible difference in frequency (ΔF) varies very greatly in different parts of the scale. Within the range from 500 c.p.s. to 4000 c.p.s. $\frac{\Delta F}{F}$ has a value of 0.003, that is, a change in frequency from 1000 to 1003, from 2000 to 2006 or from 3000 to 3009 and so on, can be detected by the average ear. The trained ear of the musician gives a still lower value. At frequencies near the lower level of audibility $\frac{\Delta F}{F}$ is about 0.01 and near the upper level (16,000 c.p.s. to 20,000

c.p.s.) tones differing very widely in frequency can scarcely be distinguished from one another. Generally speaking, pitch discrimination becomes less acute as the intensity of the sound is reduced.

When the sound intensity is kept at a constant medium value, and pitch discrimination determined over the whole audible scale, there are found to be some 1500 just perceptible differences or steps. When a sound of a constant medium pitch is gradually increased in intensity from the threshold of audibility the number of just perceptible differences in loudness is 325. One might expect that the product of these two figures would give the total number of tones which the ear can distinguish. But, owing to the fact that intensity discrimination varies with the pitch and vice versa, the number of distinguishable tones is only 340,000, not $(1500 \times 325 =) 487,500$.

FIG. 483. Chart showing the thresholds of hearing and feeling of sound at different frequencies. (After Vogel, slightly modified.)

MASKING. It is a common experience that a loud sound "drowns" a weaker one. We find it difficult to hear ordinary conversation in the roar of traffic, whereas a whisper seems loud in a quiet church. It is generally true that for any given intensity low-pitched tones have a greater masking effect than those of high pitch, that is, a high-pitched tone is more readily masked by one of low frequency than vice versa. It is not, however, the absolute frequency of the masking tone which is of so much importance, but rather the relative frequencies of the two tones, the greatest masking effect resulting when they are of nearly the same frequency. For example, a greater masking effect is exerted upon a tone of 1000 c.p.s. by a tone of 500 c.p.s. than by one of 800 c.p.s. The phenomenon of masking offers a convenient method of measuring noise. A sound generated electrically by an audiometer (p. 1047) is increased gradually until it is just perceptible to a person of normal hearing in noisy surroundings. Should it be

necessary, for example, to increase the intensity level of the audiometer tone to 50 decibels (i.e., 100,000 times) this value will be the measure of the masking or deafening effect of the noise. Masking is probably responsible for the phenomenon that persons suffering from middle ear deafness frequently hear conversation better in noisy surroundings. In this type of deafness low-pitched tones are usually affected to the greatest extent, and ordinary noise is largely made up of lower frequencies. The normal person, experiencing the effect of the noise upon his own hearing, unconsciously raises his voice which is therefore heard more distinctly by the deaf person (see also p. 1046).

The masking of one sound by another is attributed, upon the basis of the resonance theory (p. 1040), to the overlapping of the vibrations of the two tones upon the basilar membrane. But a tone in one ear is also masked by a louder tone in the other, though to a less degree than when both tones are received by the same ear; this effect must, of course, be of central origin.

The principle of masking is utilized in certain hearing tests. In testing the hearing of one ear a sound which is capable of masking the test tone is applied to the opposite ear by means of an ear-telephone. The possibility of the test tone being heard by this ear rather than by the one under examination is in this way excluded. The masking sound will of course raise the threshold in the affected ear.

THE INTERFERENCE OF SOUND WAVES; BEATS. When two tones of nearly the same frequency are sounded simultaneously they meet in opposite phases (condensations and rarefactions of the air) at one instant and in the same phase at the next. As a result of the alternate interference and reinforcement, the sound undergoes a corresponding waxing and waning. At a certain periodicity it gives rise to a disagreeable throbbing sensation analogous to flicker in vision. Each period of maximum loudness is referred to as a *beat*. According to Helmholtz's theory of dissonance, the jangling or clashing quality of discord which results when certain tones are sounded simultaneously is due to beats produced by interference between the fundamentals or the overtones of the different tones in combination.

The number of beats occurring per second corresponds to the difference between the frequencies of the two tones. For example, if one tone has a frequency of 1000 cycles per second and the other 1100, the rate of beating will be 100 per second. If the frequencies

of the two tones are nearly the same and the beats therefore recur at relatively long intervals—2 or 3 per second—they are heard very distinctly but the sensation is as a rule not unpleasant, and at the slow rate of about 4 per minute they are usually not perceived. Also, like flicker, the beats disappear if they occur very rapidly, i.e., if there is a great disparity between the frequencies of the two tones, a harmonious blend then results or a new tone called a *difference tone* (p. 1034) is heard. At a certain rate of beating between these two extremes the discordance is maximal. The frequency at which the beats disappear, as well as that at which the sensation is most unpleasant, depends upon the pitch of the lower tone, as shown in the following table of the results of Mayer's experiments.

FREQUENCY OF LOWER TONE. CYCLES PER SECOND	NUMBER OF BEATS PER SECOND		INTERVAL BETWEEN TWO TONES AT WHICH BEATS DISAPPEAR
	At which beating most unpleasant	At which beats disappear	
			<i>semitones</i>
96	16	41	6
256	23	58	4
575	43	107	3
1707	84	210	2
2808	106	265	1.5

The sensation of beats in terms of the resonance theory (p. 1040) is explained as being due to overlapping of the vibrations of two neighboring sections of the basilar membrane. Thus the amplitude of vibration of a certain region of the membrane undergoes intermittent variations; corresponding alterations in the intensity of stimulation of the auditory receptors result. The ear, like the eye, is intolerant to this form of stimulation. The greater the difference in frequency of the two tones the greater will be the distance between the two vibrating sections of the basilar membrane and the less tendency will there be for overlapping to occur and for beats to be produced. One would expect then that the spread to resonators on either side of the ones in tune respectively with the two tones would be broader at high than at low intensities and that, as a result of the greater degree of overlapping, beats would be produced at smaller frequency differences in the former instance; such an effect of varying the intensity of the sound can be demonstrated. On the other hand, two tones of nearly the same frequency which when sounded separately are inaudible, may as a result of overlapping give rise to audible beats when sounded simultaneously.

The phenomenon of beats has an interesting application in the detection of fire damp in coal mines. This gas, being lighter than air, transmits sound at greater velocity; a column of this gas has therefore a higher vibration frequency than a column of air of the same dimensions. (The vibration frequency of a column of

gas is proportional to the time taken for the sound wave to pass through it.) Two long tubes or whistles similar in every way are filled, one with the suspected mine air, the other with pure air. The two whistles are blown simultaneously; if much fire damp is contained in the air of the first tube, the frequency of the sound vibrations will not be the same in it as in the one filled with pure air, and beats will be heard. The concentration of the dangerous gas is estimated from the rate of beating.

THE LOCALIZATION OF THE DIRECTION OF THE SOURCE OF A SOUND. A visual sensation is projected very accurately to a definite point in the outside world, i.e., an object in the visual field forms an image upon a corresponding part of the retina. Sound "images" cannot, of course, be localized in the same way upon the auditory receptors, there being no spatial correspondence between the sounding body and the basilar membrane. In the judgment of the direction of a single brief sound or of an intermittent sound the most important factor is the difference in the arrival times of the sound at the two ears. If the sound reaches both ears simultaneously, it is projected to the mid-line in front or behind the head, but if the vibrations are not received at the same instant by the two ears the sound is located on the side of that ear which is stimulated first. An illusion of a sound changing its direction may be created by means of two watches which tick at slightly different rates held one to each ear. Just as with any two movements of different frequencies, the time intervals between the ticks of the two watches lengthen and shorten periodically (fig. 484). When the two ticks fall simultaneously upon both ears, a single sound is heard in the median plane either in front or behind. An instant later when the ticks become asynchronous the sound moves to the side of the faster tick, but as the intervals between the sounds lengthen they are heard separately by each ear; then as the intervals shorten again a single sound is heard which now seems to come from the side of the watch with the slower tick. Thus the sound image seems to move continuously around the head.

The effect upon sound localization of varying the time interval between the stimulation of the two ears can also be demonstrated in the following manner. A stethoscope in which the length of tubing of one limb can be altered (fig. 485) receives sound vibrations from in front and in the mid-line. When the pathway is lengthened by extending the tubing of the adjustable limb the

sound reaches the opposite ear first, and therefore seems to come from that side; upon shortening the tubing the sound is located on the side of the shorter limb.

The maximum difference in the arrival times of a sound in opposite ears at which the separate sensations fuse into one is determined by the length of the path from ear to ear, namely, 21 cm. (directly through the head). Sound is transmitted this distance through air in 0.00063 second and through the longer distance around the obstruction caused by the head in a somewhat longer time. The greatest interval between the arrival of a single sound at each ear is therefore a little longer than 0.00063 second, and this is the maximum interval between two sounds which when led to separate ears should be heard as one. By actual measurement it has been found that at intervals greater than about 0.00180 the two sounds are heard separately. The ear through experience discounts a time interval caused by the difference in distance of the two ears from the origin of the sound but recognizes any greater time interval as being due to separate sounds.

FIG. 484

The localization by the ear of a *continuous sound* cannot be explained by an interval between the reception of the sound by the two ears. When the vibration frequency is less than 800 c.p.s. a difference in phase of the sound waves striking opposite ears is the most important factor. Waves emitted from a source in the mid-line reach the two ears simultaneously and the sound is localized accordingly, but if the sound comes from one side the crest of the wave will reach the ear of that side an instant before it reaches the opposite ear. When the length of the sound wave is double the distance between the ears, namely, 42 cm., the waves fall upon the two ears in opposite phases; the wave cannot then be said to be in advance or behind the other. The ear cannot distinguish between the two phases; the sound is localized with difficulty, seeming to come from all sides. The uncertainty in localization becomes evident around 800 c.p.s. (length of wave about 42 cm.). At frequencies above from 800 c.p.s. to 1000 c.p.s. localization by phase difference fails. High-pitched sounds such as the chirp of a cricket are very difficult to locate and often seem to come from several directions at once. Some information

as to the direction of high tones is gained, however, from *differences in the intensity* or in the *quality* of the sound in the two ears. Simple tones of low pitch cannot be located through a difference in intensity in opposite ears owing to the great length of the waves (measured in feet or meters) as compared with the dimensions of the head. That is to say, the head casts no shadow for low-pitched sounds. On the contrary, sounds of high frequency (short wave length) coming from one side are shielded from the opposite ear by the head, and the difference in intensity of the vibrations in the two ears is used as a clue to the direction of the sound. The shielding effect of the skull also plays a rôle in the localization of a complex sound situated on one side or behind, even though it is of low pitch, because the higher frequencies (overtones) are screened by the skull

FIG. 485

and the auricle; the alteration in the quality of the sound caused thereby then serves as a clue. This factor is important particularly in deciding the direction of familiar sounds, i.e., those, such as voices, which have been heard upon previous occasions from different angles and hence have had their qualities impressed upon the memory.

In the localization of sounds with frequencies below 800 c.p.s. it would obviously be an advantage to have the two receptor organs separated by a greater distance than 21 cm., for any phase difference would be increased thereby. In World War I this was recognized; an apparatus consisting of two microphones separated by a difference of about two feet and connected by tubing to the ears of an observer was employed for locating enemy aircraft in flight. The application of the principle is also seen in the insect world; certain forms have paired sets of auditory receptors separated as widely as possible from one another, namely, on either side of the thorax or abdomen or, as in crickets and grasshoppers, just below the knee joints.

THE MECHANISM OF HEARING

THE EXTERNAL EAR

Though the shape of the auricle suggests that it might serve as a concave reflector to concentrate sound vibrations and direct them into the auditory meatus, its small area as compared with the length of the waves of ordinary sound, negatives the idea that it acts in this manner to any important degree. Only sounds of relatively high frequency (over 6000 c.p.s.) whose wave lengths are commensurate with the size of the auricle could be converged in this way; longer waves would tend to be scattered. The large trumpet-shaped ears of some animals, on the other hand, are of such a size as to be of real service in this respect, especially since they can be turned towards the source of the sound.

THE TYMPANIC MEMBRANE is aperiodic. That is, it vibrates unselectively to a wide range of frequencies, having no natural frequency of vibra-

FIG. 486. The response of the ear-drum to a simple sound. The unsymmetrical nature of the human ear results in parts of the simple harmonic curve, which is drawn thick, being replaced by those shown by broken lines. (After Jeans.)

tion; or rather, its natural frequency lies below the threshold of hearing. Like the well-designed diaphragm of a telephone transmitter, it does not resonate to any particular frequency but responds to all. It is forced into vibration by the sound waves and exhibits a high degree of damping, its movements stopping almost instantly upon cessation of the sound.

The tympanic membrane does not faithfully reproduce the *form* of the incident sound waves, but modifies them, the new vibratory motion being then transmitted through the ossicles to the internal ear. This behavior of the membrane is due to its asymmetry. A structure, such as the prong of a tuning-fork or the skin of an ordinary drum which is perfectly elastic and symmetrically loaded moves equal distances on either side of its resting position, its movements in response to a pure tone being simple harmonic and can be represented by a sine curve. The asymmetry of the ear drum is due mainly to the auditory ossicles to which it is connected on its inner aspect, and to the tension exerted by the intra-aural muscles.

TONES CREATED BY THE EAR; AURAL HARMONICS; COMBINATION TONES. The asymmetry of the drum membrane results in the production of tones by the ear itself, i.e., additional tones with frequencies differing from those of the incident sound. The curve in fig. 486 represents the movements of the drum membrane to a *pure* tone of 100 c.p.s. Upon analysis this curve is found to be compounded of a series of simple harmonic waves having frequencies of 200 c.p.s., 400 c.p.s., 600 c.p.s., etc. The compound wave repeats itself 100 times per second, so the original tone as well as the higher frequencies is heard. Thus, as a result of the asymmetry of the drum membrane the ear has created a new set of frequencies, adding to the original tone the octave (200 c.p.s.) and the other harmonics. These overtones, called *aural harmonics*, being purely subjective, i.e., non-existent outside the ear, cannot, of course, be detected by means of resonators.

The aural harmonics are not heard, especially those of higher frequency, unless the original sounds are fairly loud (over 45 decibels) for it is only when the vibrations reach a certain amplitude, and force the drum membrane and the structures of the middle ear to their elastic limits that they become asymmetrical. As the intensity of the sound is progressively increased harmonics of higher and higher frequencies are added to the original tone. The latter, however, always tends to obscure (mask) to a certain degree the higher frequencies. With vibrations of small amplitude, movement at the incudomalleolar joint permits equal displacements of the membrane in both directions. Also, when this joint is ankylosed, as in old age, outward and inward movements tend to become more nearly equal and the subjective tones are absent or greatly reduced. The tensor tympani muscle, by drawing the malleus inwards, tends to reduce the movement at the incudomalleolar joint. Increased tension of this muscle therefore tends to increase the aural harmonics, relaxation to diminish them.

Combination tones. When two pure tones are sounded, the ear adds not only the octave of each tone, but a *difference tone*, so called because its frequency is the exact difference between the frequencies of the two primary tones. For example, when tones with frequencies of 200 and 300 cycles per second are sounded together a compound motion will be produced which repeats itself 100 times per second. Tones of 100, 200, 300, 400, 500, 600 c.p.s., etc., will be heard. The frequencies 200 c.p.s. and 300 c.p.s. are, of course, those of the two primary tones and 400 c.p.s. and 600

c.p.s. are their octaves; 100 c.p.s. is the "difference" tone and 500 c.p.s. (the sum of the original frequencies) is called the "summation" tone.² The summation tone is always more difficult to hear than the difference tone since, being of higher frequency and weaker, it tends to be masked by the primary and difference tones.

The difference tone of 100 c.p.s. in the foregoing example is the fundamental of the tones 200 c.p.s. and 300 c.p.s., and it is generally true that whenever two or more tones which happen to be the harmonics of the same fundamental tone are sounded together with sufficient intensity, the fundamental is heard as a difference tone, i.e., the fundamental tone is created by the ear. To give another example, when the second (octave) and the third harmonics of middle C are sounded simultaneously (respective frequencies are 512 c.p.s. and 768 c.p.s.) middle C itself (256 c.p.s.) is heard.

These facts have important practical applications in telephone, talking picture and radio engineering. The diaphragm of a telephone is so constructed that it responds to the harmonics of the human voice but not to the main tones; these are added by the ear of the listener. The natural frequencies of the instrument range from 300 to 2400 c.p.s., which are above the frequencies of the main vocal tones. The latter are therefore transmitted at a scarcely audible intensity, whereas the higher frequencies—the harmonics—since they coincide with the natural frequencies of the instrument are strengthened. The deeper main tones are created by the ear. By this device exaggeration of certain of the more prominent tones of the voice is avoided. Otherwise these tones through resonance would mask other tones of higher frequencies and lower intensity which are largely responsible for the quality and intelligibility of speech. The principle has been demonstrated in a striking manner in the laboratories of the Bell Telephone Company. Two sets of gramophone records were made. A song, a conversation, instrumental music and other sounds were reproduced on one set, all the tones being faithfully recorded. The other set of records were made from the same sounds after they had been passed through filters and the fundamental tones removed. To the ear both sets of records were almost identical.

THE TRANSMISSION OF SOUND FROM THE DRUM MEMBRANE TO THE INTERNAL EAR

The vibrations of the tympanic membrane set up by air-borne sounds are transmitted to the oval window by the chain of auditory ossicles and thence to the perilymph of the vestibule. Vibra-

² Difference and summation tones are not always subjective, for under certain conditions they are produced outside the ear, as when the sounds are transmitted through some medium which like the tympanic membrane is asymmetrical, e.g., the rectifying valve of a radio set.

tions of audible frequencies are transmitted through Reissner's membrane and the scala media to the basilar membrane, then through the scala tympani to the round window (fig. 487). The compression phases of the sound waves in the external auditory meatus cause a movement inwards of the tympanic membrane and of the base of the stapes, a downward displacement of the basilar membrane and a movement outwards (i.e., towards the tympanum) of the round window. During the expansion phases of the sound waves, displacements of these structures in the reverse direction occurs. Thus are the vibrations of the drum membrane reproduced in the basilar membrane.

FIG. 487. Diagram of the passages of the cochlea straightened out to show the manner in which vibrations are transmitted from the oval to the round window through the scala media. The wavy line represents the organ of Corti.

It is quite evident that, since liquids are incompressible, no appreciable movement of the stapes could occur were there no part of the bony labyrinth which yielded to pressure. The membrane of the round window situated between the scala tympani and the middle ear yields readily, and thus permits such a movement to take place. Owing to the presence of the helicotrema (p. 1022) through which the scala vestibuli communicates with the scala tympani, vibrations of very low frequency are incapable of setting up vibrations in the membranous cochlea of sufficient force to stimulate the nerve endings; the fluid is moved *en masse* as in a U-shaped tube formed by the upper and lower galleries.

The middle ear is filled with air; vibrations of the drum membrane must therefore be transmitted to the round window as well as to the oval window. The auditory ossicles, however, provide a preferential path for the transmission of sound, serving as a mechanism for concentrating the vibrations at the internal ear. Any inward movements of the membrane of the round window which may result, since they will be opposite in phase to those of the base of the stapes, will tend to diminish rather than to enhance the force of the vibrations

of the basilar membrane. It has been found, for example, that shielding the round window by means of a pledget of cotton placed over the niche in which it lies increases the acuity of hearing.

Two factors are responsible for the intensification of the vibrations at the oval window, (a) the leverage action of the malleus and incus and, (b) the greater area of the drum membrane as compared with that of the oval window. The malleus and incus together form a bent lever of the first class, the handle of the malleus constituting the long arm of the lever and the long process of the incus, which articulates with the stapes, the short arm (see fig. 488). The axis of rotation (fulcrum) of the lever is represented by a line running through the anterior ligament of the malleus and the short process of the incus. The length of the short arm is about $\frac{2}{3}$ that of the long arm formed by the handle of the malleus. The amplitude of movement of the tip of the incudal arm is therefore only $\frac{2}{3}$ that of the tip of the long arm, i.e., the amplitude of movement at the center of the drum membrane. The matter is complicated by the fact that the base of the stapes is not moved in and out in a simple push-pull or plunger-like action but, being hinged at its posterior margin,³ executes a rocking motion; the amplitude of the movement of the posterior part of the footplate is considerably less, therefore, and that of its anterior edge considerably greater than $\frac{2}{3}$ that of the drum membrane. Should the sound be excessively loud (i.e., near the threshold for pain) the footplate, instead of moving as just described, pivots around a longitudinal axis passing through its center (Békésy). The delicate structures of the internal ear are further protected from violent vibrations by the momentary dislocation of the incudomalleolar articulation. Instead of engaging in the usual way the surfaces glide over one another, like a slipping motor clutch, with consequent loss of energy and reduction in the amplitude and force of the vibrations. The protective rôle played by the intra-aural muscles has been mentioned (p. 1021).

The ratio of the long arm of the lever to the short arm being 3 to 2, one would expect an increase of $\frac{3}{2}$ in the force delivered at the oval window over that incident upon the tympanic membrane. Actually, the energy lost in transmission (in overcoming the inertia of the ossicles)

³ According to Wilkinson, the base of the stapes pivots around an axis passing through the junction of its posterior and middle thirds.

and the damping effect of the surrounding air more than offset the mechanical advantage gained by leverage. Were no other factor involved the vibrations would have a force only half as great at the oval window as at the drum membrane. But the area of the latter is some 20 times greater than that of the oval window. This alone by concentrating the sound waves would increase their force upon the smaller area twenty-fold. But the loss in transmission, as just stated, is about 50 per cent; which means that the force incident upon the drum membrane is about $\frac{1}{10}$ of that upon the oval window. This increase in force of the vibrations with relatively little change in amplitude is of considerable importance. It appears that a change of just such a nature is required for the most efficient transference of vibrations from a medium of low resistance, namely air, to

FIG. 488. Model illustrating the transmission of sound vibrations from the drum membrane to the organ of Corti. (From Lythgoe after Beatty.)

one of greater density and high resistance, such as the fluid of the internal ear.

BONE CONDUCTION. The auditory receptors are stimulated by sound transmitted through the bones of the skull. In man the most direct and effective bony pathways for the conduction of sound to the internal ear is furnished by the trabeculae in the subaditus region. Injury to this region, as by fracture, results in impairment of bone conduction. In order for sound to be perceived to any important extent through bone the sounding body must be in contact with the skull (e.g., mastoid process); bone conduction of air-borne sounds impinging upon the head is very slight. The sound is transmitted through the bone as through any solid, as a train of alternating compressions and expansions. Owing to the presence of the oval and round windows, chiefly the latter, serving as outlets for pressure variations, adequate movements of the basilar membrane are permitted to take place. When the base of the footplate is immovably fixed in the oval window, the round window alone serves such a purpose. The waves of compression, according to

Békésy, exert their effect mainly upon the semicircular canals from which fluid is forced into the vestibule. For this reason, and also owing to the greater resistance offered at the oval window, the pressure in the scala vestibuli is elevated more than that in the scala tympani. With each wave of compression the basilar membrane therefore moves downwards and the membrane of the round window outwards.

In a person with normal hearing, obstructing the external auditory canal by the finger increases the loudness of bone-conducted sound. This is attributed to the compression of the air in the canal by the vibrations of the skull, the sound being thus transmitted through the ossicles to the internal ear as in ordinary air transmission. The threshold for bone conduction is given by Békésy as 3.5×10^{-9} cm. movement of the skull for a tone of 800 c.p.s.

STIMULATION OF THE HAIR CELLS. The tips of the hair cells are embedded in the under surface of the tectorial membrane. An upward movement of the basilar membrane should cause bending of these processes and compression of the bodies of the cells; a downward movement of the membrane would, on the other hand, cause traction upon the processes, and possibly some elongation of the bodies of the cells. It is not definitely known which of these movements is responsible for the stimulation of the nerve endings. The nature of the immediate stimulus is also a matter for conjecture; it may be mechanical, electrical (see cochlear potentials, p. 1038) or chemical. A theory of chemical stimulation has been proposed by Hallowell Davis. He suggests that the compression of the sensory cells by the upward swing of the basilar membrane, i.e., when the base of the stapes moves outwards, causes the liberation of a chemical substance which, acting upon the sensory endings, sets up the nervous discharge.

THEORIES OF PITCH PERCEPTION

There has been relatively little room for dispute concerning the functions of the middle ear. The mechanism of the internal ear, on the contrary, has been for many years a subject of lively controversy to which both physiologists and physicists have contributed. The appreciation of pitch has been the pivot around which discussions of cochlear functions have turned, and the several theories which have been proposed are attempts to explain this extraordinary faculty of the auditory mechanism.

All theories of hearing can be divided into two main categories. In one group (a) are placed those theories which attribute the estimation of

pitch, and in consequence the ability to analyze a complex sound into its components, to the cerebral centers, and in the other (b) those which maintain that sound analysis is purely a function of the cochlea. None of those coming under the first heading is acceptable as a complete theory of hearing; one, namely the telephone theory, will be briefly described.

The telephone or frequency theory was formulated by Rutherford in 1886. The diaphragm of a telephone transmitter converts sound vibrations into electrical impulses (actually, rhythmical variations in current strength) of the same frequency. The electrical impulses conveyed by wire to the receiver of the instrument set up vibrations in a diaphragm which reproduces the original sound. If we substitute the basilar membrane for the diaphragm of the telephone, the electrical impulses for nerve impulses, the wire for the auditory nerve and the reproduced sound in the receiver for the auditory sensation, we then have a rough outline of the telephone theory of hearing. In this theory the basilar membrane is supposed to vibrate as a whole, i.e., like the diaphragm of the telephone transmitter, not selectively according to the principle of resonance. The telephone theory postulates, therefore, that *the cochlea possesses no faculty of sound analysis, the frequency of the impulses transmitted over each fiber of the auditory nerve being the sole basis for the estimation of pitch.* The intensity of sound is, according to this theory, a function of the number of active nerve fibers.

The relatively low frequency (less than 1000 per second as compared with from 20,000 to 30,000 c.p.s. for the highest audible pitch) at which the nerve fiber can conduct impulses has always been an insuperable objection to the telephone theory. This point will be discussed in the next section.

THE WEVER AND BRAY PHENOMENON

In 1930 Wever and Bray made the surprising discovery that spoken words and other sounds entering the ear of a decerebrate animal were faithfully reproduced when electrodes were placed upon the auditory nerve and connected through a valve amplifier with a telephone receiver or loud speaker. It was at first thought that the sounds emitted by the telephone receiver were due solely to action currents (i.e., to nerve impulses) of the same frequency as the sound vibrations received by the animal's ear. If this were true it would mean, of course, that the quality of sensation is correlated with the frequency of impulses in the nervous discharge and would therefore be con-

trary to observations upon other senses, for all recent work indicates that impulse frequency varies only with the *intensity* of the stimulus. Such a conclusion implies also that the analysis of sound is a function of the cerebral cortex, as postulated by the telephone theory. As a result fresh interest in this theory was aroused.

Saul and Davis in later experiments demonstrated that there are two components in the electrical potentials picked up from the nerve, namely, *true action potentials* (nerve impulses) resulting from the excitation of auditory nerve endings in the cochlea, and electrical potentials generated within the cochlea as a result of the distortion of non-nervous structures by the sound waves. These latter effects are referred to as the *cochlear response*, *aural microphonics* or *cochlear potentials*. In records showing both types of electrical effect the action potential waves are superimposed upon the aural microphonics.

The cochlear response differs from the action potentials in the following respects. General anesthesia abolishes the action potentials but not the microphonic effect. The action potentials are also affected much more by cooling the cochlea, and they disappear much sooner after the death of the animal. Arrest of the blood supply to the cochlea rapidly abolishes both responses. The latent period of the action potential (up to 0.83σ) is much longer than that of the aural microphonics (0.1σ). The cochlear potentials can be recorded from any part of the internal ear or even from any part of the skull, provided that the amplification is adequate. (They are obtained most readily with the differentiated electrode at the round window and the indifferent electrode inserted into the muscles of the neck.) The action potentials can be recorded only from the auditory nerve or some part of the auditory pathway, e.g., cochlear nuclei of the medulla, lateral lemniscus, etc. The cochlear potentials have a much greater tendency to spread through the tissues, especially over meningeal surfaces; it is owing to such spread that they can be picked up from the auditory nerve. The waves of the two responses differ in shape, the wave form of the cochlear potential being almost identical with that of the stimulating sound. The action potentials synchronize with the sound waves up to a maximum of 3000 per second (see p. 1039), whereas the cochlear potentials follow the vibration frequency up to 16,000 cycles per second, and it is probable that with more delicate methods of recording a correspondence between the cochlear potentials and the sound waves up to the limit of audible frequencies, namely, 20,000 or more cycles per second, could be demonstrated. Finally, the cochlear potentials

show summation, whereas the action potentials are of course "all or none."

Several theories as to the mode of origin of the cochlear potentials have been offered. Davis and his associates believe that they are due to pressure variations upon the hair cells induced by the sound waves; they therefore come under the head of *piezo-electric currents* such as are generated by pressure upon a quartz crystal. According to Davis, a potential difference is created between the bases and free ends of the hair cells when these cells are compressed against the overlying tectorial membrane, that is, when the footplate of the stapes moves *outwards* and the basilar membrane swings upwards. In support of his contention Davis cites experiments upon animals (albino cats and waltzing guinea-pigs) in which the organ of Corti was congenitally absent or the hair cells *abnormal* and no aural microphonics could be obtained. Moreover, certain chemicals, e.g., crystals of sodium chloride, applied to the internal ear injure the hair cells and depress the cochlear response, and when degenerative changes were induced in the mid-region of the basilar membrane of dogs by a loud tone of *medium pitch* (p. 1042) sounded over a long period, this particular sound was not heard by the animal nor was it followed by a cochlear response.

The physiological function, if any, of the cochlear potentials is unknown. They appear to be rather of an accidental occurrence—an epiphenomenon of auditory function. However, this much can be said; hearing may be lost though the aural microphonics persist unimpaired, but hearing is never retained in their absence.

Evidence that vibrations of resonant structures in the cochlea are responsible for the aural microphonics has been secured by Walzl and Bordley. They have succeeded in injuring selected and limited regions of the organ of Corti, without separation of Reissner's membrane on the basilar membrane; and have studied the effects of such injuries upon the cochlear potentials. Damage near the base of the cochlea was found to raise the threshold for high tones, while injury near the apex was followed by impairment or loss of the response to sounds of low frequency. These results point to elements—most probably the hair cells of the organ of Corti—attached to a particular level of the basilar membrane, and thus tuned to particular sound frequencies: they give strong support for a place theory of hearing (p. 1041).

Impulses recorded from the auditory nerve and brain. Action potentials free from microphonic effects can be picked up from the auditory nerve

by means of coaxial electrodes (described on p. 786). The latency of the action potentials is between 0.53 msec. for sounds of the highest intensity and 0.83 msec. near the threshold of audibility. The impulses are synchronous with the sound waves up to about 3000 c.p.s.; above this frequency there is no correspondence between the two. When a sound with a frequency less than 900 c.p.s. is gradually increased in intensity a point is reached at which the action potential is maximal. If the intensity is kept at this level but the frequency raised above about 900 c.p.s., the amplitude of the waves falls sharply to about half of their previous value; at 2000 c.p.s. the amplitude is reduced to one-third and at 3000 c.p.s. or so, to a very low value. It must be remembered that the electrodes placed upon the intact nerve record potential changes from a number of fibers almost simultaneously. The recorded waves are, therefore, composite in nature and vary in amplitude with the number of functioning fibers. The step-like fall in amplitude as the frequency is raised from 900 to 3000 c.p.s. is due to a corresponding reduction in the number of active fibers and this reduction is the result, in turn, of the impulses falling each in the relative refractory period (p. 787) of its predecessor. Now the absolute refractory period of a fiber of the auditory nerve is about $\frac{1}{1000}$ second. In other words, a single fiber cannot conduct more than 1000 impulses per second. Therefore, when the sound vibrations reach a frequency of between 900 and 1000 c.p.s., the fibers respond only to every other stimulus. But the refractory periods of all the fibers do not begin and end at the same instant; this allows half the fibers to respond to *alternate* vibrations and the nerve as a whole to respond to every vibration though, as just stated, the amplitude of the action potential is reduced by half. At a vibration frequency of 2000 or 3000 c.p.s. the individual fibers respond to every third or fourth vibration, respectively. Yet again, since the refractory periods are not coterminous, the fibers function in *rotation*, and the nerve as a whole is capable of answering to every stimulus; the amplitude of the action potential is diminished in proportion to the number of inactive fibers.

Thus, the limited correspondence of the auditory impulses with the frequency of the stimulating sound is a phenomenon which is due, apparently, to the fact that the auditory nerve is a composite record of the potentials in a number of separate nerve fibers. The fiber responds to a definite

phase of the stimulating wave-cycle, but each fiber in a group does not necessarily respond to the same wave; so, the frequency of the impulses in a *single fiber* may be very much lower than that of the stimulating sound. Galambos and Davis have recorded the impulses from a single fiber by means of a glass microelectrode inserted into the auditory nerve. The nerve was exposed through an opening in the temporal bone and the electrode adjusted by a micromanipulator until a single series of impulses appeared in the record. The findings of Galambos and Davis are entirely in accord with a place theory of hearing (p. 1041). The isolated auditory fiber was found to behave in the same manner as does any other sensory nerve. At threshold intensity it responded to a narrow band of sound frequencies; the impulse frequency varied only with changes in the *intensity* of the sound. The maximum frequency of the impulses, 400 per second, was recorded when the sound was increased to 30 decibels above threshold intensity. At the higher sound intensities the fiber reacted less specifically, responding to frequencies within a wider range. In some instances a very loud sound, even an octave below the band of frequencies to which the response of the fiber was restricted at threshold intensity, caused a discharge of impulses.

Impulses can be recorded by means of electrodes inserted at various levels along the auditory pathway, e.g., the cochlear nuclei, the trapezoid body, the lateral lemniscus, the medial geniculate body or the inferior colliculus, and even from the auditory radiation and auditory cortex. At the higher levels the frequency at which synchronization of impulses and sound waves ceases is much lower than in the auditory nerve. The number of synapses which the impulses must cross is apparently the factor responsible for depressing the synchronization limit. At the inferior colliculus synchronization is not evident, as a rule, above frequencies of 1000 c.p.s. and not above 20 c.p.s. in the auditory radiation or cerebral cortex.

Now the highest audible frequency is from 20,000 to 30,000 cycles per second (p. 1030). It is quite evident therefore that the telephone hypothesis or any other based upon the assumption that the brain receives impulses of the same frequency as that of the incident sound can no longer be entertained.

The organ of Corti is projected to the medial geniculate body, which constitutes the primary auditory center, and to the acoustic area of the

cerebral cortex. In both these regions a spatial differentiation according to sound frequencies has been demonstrated. The dorsal part of the medial geniculate body responds to frequencies of around 8000 c.p.s., the anterior and lateral parts to 4000 and 2000 c.p.s., respectively, and the posterior part to 1000 c.p.s. Cycles of 500 per second and less are recorded in the central portion. In the acoustic area the apical turns of the organ of Corti are represented anteriorly and the basal turns posteriorly.

THE RESONANCE OR HARP THEORY

Though it was suggested as long ago as 1761 by Cotugno of Naples and in 1826 by Sir Charles Bell of Edinburgh that the ear owed its faculty of pitch perception to resonating structures in the labyrinth, it was not until 1863 that the scientific foundations of the resonance theory were laid. In this year Helmholtz published his now famous work entitled *Sensations of tone as a physiological basis for the theory of music*, in which he gives an account of a brilliant series of physical and physiological studies of hearing.

The resonance theory postulates that the analysis of sound into its constituent frequencies is primarily a function of the cochlea, that the fibers of the basilar membrane constitute a series of resonators, and that the part or level of the membrane at which the fibers are set into maximal vibration by the sound waves is the sole basis upon which the brain rests its judgment in discriminating differences of pitch.

The fibers of the basilar membrane which in deference to the resonance theory are frequently referred to as the *auditory strings*, number about 24,000. Each arch of Corti, of which there are some 5000, is associated with 4 or 5 auditory strings. The combined structure, rather than each one of the 24,000 fibers, should probably be regarded as a resonating unit. In this theory the resonating structures are compared to the strings of a harp or pianoforte; they are believed to vibrate in sympathy with the sound waves, i.e., each resonator responds to the frequency corresponding to that of its own free vibration (p. 1026). We have seen (p. 1023) that the fibers increase progressively in length from the base to the apex of the cochlea, a fact quite in accord with the resonance theory.

Upon first thoughts one would likely conclude that this resemblance of the basilar membrane to a stringed instrument must be mere coincidence

and that it is rather fantastic to compare a structure only 30 mm. long and 0.5 mm. wide at its broadest part with a piano or harp in which the longest (bass) wires are measured in feet. Furthermore, the auditory range is some 11 octaves and some 1500 separate tones can be distinguished by the ear, whereas the pianoforte extends over only 8 octaves, containing some 96 separate notes. But factors other than length, namely, tension and mass (p. 1028) determine the vibration frequency of a stretched string. There is reason to believe that the basilar fibers are differentiated as to tension, the loosely stretched fibers being at the apex where the flimsy character of the external spiral ligament seems to indicate that it exerts here the minimum degree of traction upon the basilar membrane. In the basal turn the external spiral ligament is several times thicker than at the apex,

FIG. 489. Illustrating liquid loading of the auditory strings. See text. (After Beatty.)

which suggests that in this part of the cochlea the basilar fibers are at their greatest tension. Yet, even granting that the longest auditory strings are at minimum tension, their mass would need to be greatly increased in order that they should be capable of vibrating at the lowest audible frequency, namely, 16 cycles per second. Now, the bass strings of the piano are, of course, of greater length and lower tension than the strings of the treble, but their low frequency of vibration is secured largely by increasing their mass. The greater mass is obtained not so much by increasing the thickness of the wire (for this would greatly reduce its flexibility) but by a helix of copper wire, i.e., by a wire coiled around it. By means of such loading of a comparatively short thin wire, a vibrating element is obtained with a low frequency yet sufficiently flexible and of convenient length.

The auditory strings are loaded by the cellular structures of the basilar membrane (see p. 1023) and also, to a greater extent, by the fluid in which they are immersed. This liquid load, according to Wilkinson, is the column of fluid extending upwards from the oval and round windows to the

basilar fibers resonating at the moment. The length of the fluid column will vary, of course, with the level of the vibrating fibers, i.e., with their distance from the oval and round windows.⁴ According to this conception of liquid loading the auditory strings are differentiated with respect to mass as well as according to length and tension, the shortest fibers at the base of the cochlea (i.e., nearer the oval and round windows) being loaded with the shortest liquid columns, the fibers at the apex with the longest columns. This principle of liquid loading is illustrated in fig. 489.

In order to account for the very high frequency (20,000 to 30,000 c.p.s.) of the auditory strings at the base of the cochlea, one must suppose that the fibers in this situation are under a tension which, to opponents of the resonance theory, has seemed incredibly high. The length of the shortest basilar fiber is in the neighborhood of 0.16 mm. Such a fiber in order to be in tune with the highest audible frequency would need to be under a tension of nearly 4 tons per square inch (Beatty). Yet such a stretching force, enormous as it is, does not exceed the bounds of possibility when the strength of other biological materials is considered. A human hair, for example, can sustain a stress of 9 tons per square inch, a spider's thread, 12 tons per square inch and silkworm gut, 32 tons per square inch.

The basilar fibers are embedded in a homogeneous ground substance which by binding them into a continuous structure prevents them from vibrating separately; for this reason it would seem that they could not act as a series of resonators. This apparently insuperable objection to the resonance theory has been met by the conception of *maximum stimulation* advanced by Gray. For example, a sound sets into vibration not only those basilar fibers which are in tune with it, but also, though less forcibly, those for a variable distance on either side. This assumption is in agreement with observations upon pitch perception after auditory fatigue (p. 1028). It follows that there will be a central fiber or small group of fibers which vibrates maximally and other "out of tune" fibers which vibrate submaximally, the amplitude

of vibration decreasing progressively with the distance from the "in tune" or central resonators. Only those vibrations of maximal amplitude, it is claimed, lead to effective stimulation of the nerve endings. This concept of maximal stimulation is not merely an ingenious hypothesis, for the same principle appears to be the basis of cutaneous localization. When a pointed object is pressed upon the skin, e.g., on the finger tip, the sensation is restricted to a single small area; even with deep pressure one feels only a sharp point. Yet the skin for an area of several square millimeters surrounding the point of maximal stimulation is deformed sufficiently to arouse a definite sensation were the stronger stimulus absent.

It is also pointed out by Wilkinson that in order for the liquid columns to load the membrane in the manner described, it is necessary that the

We are therefore justified in accepting a "place" theory of pitch appreciation. There is a formidable array of evidence for the belief that the localizing mechanism comprises the fibers of the basilar membrane acting as a graduated system of resonators. The projection of the organ of Corti to the primary auditory center (p. 1025) and to the cerebral cortex with the preservation of a spacial arrangement also speaks for a place theory.

Observations and experimental results bearing upon the questions discussed in this section will be briefly cited (see also p. 1039).

(1) *The structure of the cochlea.* It is scarcely reasonable to regard the design of the cochlea, which upon close examination appears to be so admirably adapted to the selective reception of vibration frequencies, as being quite without meaning. Surely a much simpler mechanism would suffice for the stimulation of the nerve endings were the analysis of sound undertaken by the cerebral centers.

(2) A change in the form of a sound wave caused by simply altering the phases of the combined waves in relation to one another does not alter the pitch or quality of the sound. This fact alone is strongly in favor of the resonance theory and the results of an ingenious experiment performed by Hartridge lend further support. The phase of a tone sounded by a siren was altered by half a wave length (180°). The change in phase caused a brief period of silence (the "phase change beat"), the tone then returned and increased rapidly to its original intensity; there was no change in pitch. This phenomenon is taken as indicating the existence of resonators in the cochlea, being compared to the effect caused by a troop of men marching in step across a suspension bridge and then suddenly and in unison changing step. When the change in step is made, the bridge, which had been vibrating "in tune" with the tramping feet, is brought to rest for an instant, since the steps are now out of phase with its vibrations. But after this momentary period of "silence" the structure again picks up the rhythm, its motions soon reaching their previous amplitude.

(3) *The correlation of lesions localized to definite cochlear levels with loss of hearing over limited ranges of pitch.* (a) Boilermakers and others who work amidst loud, clanging sounds sometimes become deaf to tones of the same pitch as that of the noise, though retaining their hearing over other parts of the scale. Degenerative changes are found in that part of the basilar membrane which in accordance with the "place" theory corresponds to the range of the deafness. (b) Crowe and his associates examined *post mortem* the internal ears of 79 subjects of high tone deafness. Three-quarters of these showed atrophy of the organ

of Corti in the basal turn, or of the nerves supplying this part of the cochlea. These changes were much more extensive and severe than any found in the ears of 200 subjects with normal hearing. (c) "Islands" of hearing can sometimes be demonstrated in persons congenitally deaf to all other tones. It is impossible to account for such a phenomenon by any theory which attributes sound analysis to the cerebral cortex. It is inconceivable that the brain can perceive one set of impulse frequencies but fails in respect to all others, or that the basilar membrane vibrates as a whole to certain small ranges of vibration frequencies, as the telephone theory demands, but is unresponsive to those higher or lower in the scale. (d) The experiments of Witmarch and later of Yoshii and other investigators afford important evidence of some mechanism whereby sound vibrations are localized upon the basilar membrane according to their frequencies. Guinea-pigs were exposed over long periods to loud sounds of constant pitch. When the stimulating tone was of high frequency histological examination of the cochlea after death revealed degenerative changes in the organ of Corti of the basal turn, tones of medium pitch resulted in similar changes in the middle turn; structural changes at the apex were not produced, however, by tones of low pitch. Pavlov has shown, however, by the conditioned reflex method that destruction of the upper part of the cochlea in the dog causes deafness to frequencies below 600 c.p.s. (see footnote, p. 915). (e) Davis and Derbyshire and associates have recently investigated the effects of prolonged stimulation upon the labyrinth of guinea-pigs and upon the threshold of the electrical response of the cochlea. It was found that exposure for 75 days to frequencies of from 600 to 800 c.p.s. and intensities of from 60 to 95 decibels occasionally produced slight wide-spread cochlear damage and a corresponding rise in the threshold of the cochlear response. However, exposure to tones of 2500 c.p.s. and intensities of about 100 decibels for 40 days or so caused more or less extensive damage of the external hair cells of the organ of Corti in the middle part of the second turn of the cochlea and a corresponding rise in the threshold of the cochlear response, the highest threshold being for tones of 1200 c.p.s. In previous experiments it was shown by these observers that the cochlear response was a reliable index of auditory function, for its threshold was found to agree with that as determined by the method of conditioned reflexes. (f) Stevens, Davis and Lurie recorded the electrical response before and after drilling through the cochlear wall at different levels and damaging the organ of Corti. Good correlations were obtained between the levels of the lesions and the changes in threshold of the cochlear responses at corresponding frequencies. The diagram shown in fig. 490 was drawn from the results of these experiments.

THE BASIS FOR THE PERCEPTION OF LOUDNESS.

We have seen in considering the sense organs that the frequency of the impulses discharged along the individual nerve fibers, and probably also in some instances at least the number of functioning fibers, are the factors determining the intensity of the resulting sensation (p. 808). The loudness of a sound is now also believed to be dependent upon the frequency of the impulses in the individual nerve fiber and, but to a more important extent, upon the total number of active fibers. With a

sound of low intensity a narrow section of the basilar membrane tuned to a particular wave frequency is set into vibration and relatively few fibers are stimulated, whereas a loud sound sets in motion the basilar membrane on either side of this region of maximum vibration and a much larger number of fibers is stimulated. Thus, to quote Hallowell Davis “—pitch is a function of *where*, while intensity is a function both of *how much* of the basilar membrane is disturbed and of an increase in the rate of discharge of many of the activated fibers.”

CHAPTER LXXX

THE EUSTACHIAN TUBE. DEAFNESS. HEARING TESTS. THE HARMFUL EFFECTS OF NOISE

THE FUNCTION OF THE EUSTACHIAN TUBE.
THE EFFECTS OF OCCLUSION. The Eustachian tube affords the only means whereby the pressure of air within the middle ear can be equalized with that of the atmosphere. The pharyngeal orifice of the tube is closed at ordinary times, but opens during swallowing, yawning or when a high pressure is created in the nasopharynx, as by blowing the nose or making a forced expiration with the nostrils and mouth closed (Valsalva's experiment). During swallowing the orifice is opened by the contraction of small muscles—the *salpingopharyngeus* and *dilator tubae*—attached to its margins. The pressure within the tympanum may be raised above atmospheric pressure by the accumulation of inflammatory exudate, or become subatmospheric as a result of occlusion of the Eustachian tube. In the latter event air is gradually absorbed from the middle ear into the blood stream (see p. 370) and the partial vacuum thus created causes retraction of the drum membrane. The inward displacement of the membrane may be so great as to bring it into contact with the inner wall (promontory) of the tympanum, the cavity being almost obliterated. Deafness results, which is relieved by catheterization of the Eustachian tube or by inflating the ear by means of a Politzer bag, and thus equalizing the pressure on the two sides of the membrane. Temporary occlusion of the tube caused by swelling of the mucous lining is not an uncommon occurrence during an ordinary cold. A sensation of fullness in the ears is experienced, and usually some loss of hearing which is quickly relieved, as a rule, by swallowing or by blowing the nose and thus forcing air up the Eustachian tube. The latter practice is decidedly risky since it is likely to force infective material into the ear and cause acute inflammation.

The tympanic membrane is very sensitive to any difference in pressure on its two surfaces, and during rapid changes in altitude, as in aeroplane ascents and descents, annoying aural effects may be produced. In experiments reported by Armstrong and Heim, bulging of the membrane accompanied by a sensation of fullness occurred when the atmospheric pressure was reduced by an amount corresponding to an altitude of from 100 to 180 feet. When the reduction in pressure

amounted to 15 mm. Hg, which corresponds to an elevation of 500 feet above sea level, a distinct "click" was felt in the ear as the drum membrane snapped back into its normal position. These effects were due to the higher pressure in the tympanum forcing the Eustachian tube and thus equalizing the pressure on the two sides of the membrane. With further progressive reduction in atmospheric pressure a similar sequence of events was observed, except that the successive "clicks" occurred with a reduction in outside pressure of only 11.4 mm. Hg. This is taken to indicate that the pressures within and without the tympanum are not fully equalized at these altitudes, but that, though the Eustachian tube is forced open at an excess pressure of 15 mm. Hg in the middle ear, closure of the tube occurs while the inside pressure is still 36 mm. Hg above that of the atmosphere.

The results of raising the outside pressure above that in the middle ear, as in aeroplane descents, are quite different. The Eustachian tube acts like a valve, remaining firmly closed against any degree of external pressure. Up to a pressure of from 80 to 90 mm. Hg, the tube can be opened by swallowing, but at pressures greater than this the walls of the lower part of the tube are collapsed and held so firmly in this position by the partial vacuum in the middle ear that the dilator muscles are powerless to open it. Rupture of the drum membrane which, according to these observers, is accompanied by severe piercing pain, a loud explosive report in the ear and a sensation of being struck on the side of the head, occurs when the difference in atmospheric pressure and the pressure in the middle ear is from 100 to 500 mm. Hg. Nausea, vertigo and general shock are experienced. A pressure difference great enough to rupture the drum membrane in a conscious person is unlikely to occur unless the descent is very rapid (4000 feet per minute) because, even though there is no sensation to give warning of the increased pressure upon the ear drums, most persons swallow automatically every minute or so. Rupture of the membrane might easily occur, however, during sleep, in an unconscious patient in a hospital plane, or in a person with an occluded Eustachian tube.

DEAFNESS. Defective hearing may result from disease or abnormality affecting any part of the auditory mechanism. The transmission of sound to the internal ear may be interfered with as a result of some obstruction in the external auditory meatus, of failure of the Eustachian tube to maintain communication between the pharynx and the

middle ear, or of some disease or defect of the middle ear itself. Loss of hearing resulting from any of these causes is termed *transmission* or *conductive deafness*. Deafness due to loss of function from whatever cause of the receptor organs of the internal ear or of the auditory nerve is termed *perceptive deafness*, and that resulting from a lesion of the auditory pathways or of the auditory center is called *central deafness*.

Transmission deafness. Wax or a foreign body in the external auditory meatus or some developmental abnormality of the external ear may, by shielding the ear drum from the sound, cause deafness which, of course, varies in severity with the degree to which the meatus is obstructed. Deafness, usually of a temporary nature, commonly results from acute inflammation of the middle ear—*acute otitis media*—which is caused in the great majority of instances by the passage of infective material from the nasopharynx along the Eustachian tube during an ordinary cold, influenza or sore throat. During the acute stage of otitis media the ear becomes filled with fluid and is very painful; the accumulation of fluid raises the pressure within the tympanum and bulges the ear drum outwards. The inflammation may progress to pus formation which, if the condition is left to itself, is followed by perforation or rupture of the drum membrane. The surgeon endeavors to prevent rupture by making an incision at a dependent point so as to provide free drainage. The incision soon heals, leaving, as a rule, little or no loss of hearing.

Chronic or subacute otitis media causes progressive impairment of hearing due to fibrous adhesions which limit the movements of the ossicles, ankylosis of the incudomalleolar joint, or fixation of the base of the stapes in the oval window. Other factors which may be responsible for the loss of hearing are thickening of the drum membrane and occlusion of the Eustachian tube. In chronic middle ear disease the subject as a rule suffers a greater degree of hearing loss in the lower and middle tones of the scale; in perceptive deafness hearing is impaired mainly for the higher frequencies.

Otosclerosis is a chronic ear affection associated with progressive loss of hearing, especially for low tones. The deafness is due to osseous changes which commence in the outer wall of the labyrinth, particularly around the margins of the oval window. Limitation of movement of the base of the stapes results, the ossicle ultimately becoming fixed in the oval window. The pathological process commences with absorption of bone; this is followed by osseous overgrowth, the new formation having the structure of osteoid tissue containing wide spaces filled with connective tissue, rather than of true bone. Osteoblasts are numerous. The disease extends inwards, involving the bony labyrinth; degeneration of the hair cells of the organ of Corti is

found in most instances. Several theories have been proposed to account for otosclerosis, namely, that it is due to a disturbance of calcium metabolism associated with parathyroid dysfunction, that it is caused by infection following inflammation of the middle ear, or that it is a reaction set up by diminished blood supply to the osseous labyrinth caused by vascular sclerosis. Little evidence can be cited in support of any of these theories. The disease shows a familial tendency.

When the footplate of the stapes is rigidly fixed in the oval window the function of transmitting air-borne vibrations to the perilymph devolves upon the round window. The membrane here must then vibrate in sections which move in opposite phases—as one part of the membrane moves in the other moves out. The amplitude of the movements is minimal. For the reason mentioned on page 1035 no appreciable movement of the membrane as a whole is possible. An operation devised by Holmgren and modified by Sourdille, by Lempert and by others, with the view of increasing the amplitude of vibration of the basilar membrane in otosclerosis has so far yielded most encouraging results. The surgical procedure consists in drilling through the osseous wall of a horizontal semicircular canal and covering the gap with a cutaneo-membranous flap reflected from the depth of the external auditory canal and the adjacent portion of the tympanic membrane. By thus providing an artificial second window, pressure variations incident upon the round window are readily transmitted through the internal ear.

Perceptive deafness may result from injury which causes detachment of the sensory cells of the organ of Corti, from inflammatory conditions of the labyrinth, from degeneration of the sensory cells following prolonged and strong stimulation (p. 1040) or from injury or disease of the auditory nerve, such as fracture of the base of the skull or tumor in the region of the cerebello-pontine angle. A tumor in the latter situation is likely to involve the vestibular division of the nerve as well. Deafness is not infrequently due to a developmental defect of the internal ear, the degree of deafness varying in different instances from a slight impairment to deaf-mutism. The latter condition, though frequently congenital, may result from some disease of the ear during infancy which leads to complete loss of hearing. In deaf-mutes the semicircular canals are not infrequently undeveloped as well as the cochlear part of the labyrinth; in such persons the responses to the ordinary tests of vestibular function (e.g., rotation, p. 839) are absent.

Central deafness. A unilateral lesion of the lower part of the auditory pathway, e.g., in the medulla, before any of the fibers of the cochlear division have crossed to the opposite side of the brain stem causes loss of hearing in the ear on the side of the lesion. But some fibers ascend uncrossed, thus each ear is bilaterally represented in the cerebral cortex. A uni-

lateral lesion of the auditory pathways anywhere above their decussation therefore causes little or no impairment of hearing, and any which may result affects both ears. Slight if any loss of hearing follows the complete surgical removal of one temporal lobe.

Paracusis Willisii is the term given to the curious phenomenon first described by Willis (1630), that a deaf person hears better in noisy surroundings, as in traffic, trains, etc. There are two main forms—false and true. *False paracusis* is common and easily explained upon the basis of masking (p. 1031). *True paracusis* is rare; there is a real increase in auditory acuity, for it is not only conversation which is heard better but a sound kept at a constant intensity is also rendered more distinct by the presence of noise. The phenomenon has not received a satisfactory explanation. Some believe that it occurs only when there is some stiffness in the articulations of the ossicles. The noise vibrations, it is thought, by “shaking up” the joints render the ossicular chain more efficient in transmitting other weaker sound waves. Other suggestions are that the noise increases the blood supply to the cochlea, or that through the jarring effect of the vibrations the auditory nerve is rendered more irritable.

HEARING TESTS

Disease confined to the middle ear affects the transmission of air-conducted sounds only; conduction through the bones of the skull is not interfered with. When, for example, a vibrating tuning-fork is held to the ear of a subject with middle ear disease, he may fail to hear it, but when the shaft of the fork is pressed against his skull (e.g., the mastoid process) the sound is heard at least as well by him as by one with normal hearing. In deafness due to disease of the internal ear or of the auditory pathway the perception of bone-conducted sounds as well as those transmitted through the middle ear is impaired.

The following tests are employed to distinguish perceptive from transmission deafness.

Weber's test. The tone of a tuning-fork applied to the forehead of a person with normal hearing is referred to the mid-line. In unilateral middle ear deafness the sound is localized in the diseased ear, whereas in deafness due to disease of the labyrinth or of the auditory nerve of one side it is heard best or only in the normal ear. This apparently arbitrary result is to be explained upon the basis of masking. In unilateral middle ear deafness, the cochlea of the affected side is shielded from air-borne sounds as a result of defective transmission, whereas on the normal side the tone is masked; it follows that in a perfectly silent room the sound would not be localized to either side. A person with normal hearing ordinarily hears more acutely in one ear if the opposite ear is closed by the finger, but in

perfectly silent surroundings the hearing in one ear is not improved by blocking the other. *Rinne's test.* Each ear is tested separately, the auditory meatus of the opposite side being blocked by the observer's finger. A vibrating tuning-fork is applied to the mastoid process; when the sound is no longer audible to the patient the fork is brought close to the corresponding auditory meatus. The subject of middle ear deafness does not hear the sound after it has ceased to be heard through the bone; the test is then said to be negative (*Rinne negative*). A person with a normal middle ear hears the sound for a short time through the air after it is inaudible through bone (*Rinne positive*). *Schwabach's test* consists of the accurate measurement in seconds of the time interval during which the sound is heard through bone (bone-conduction test) or through the air (air-conduction test). Or the length of the interval in each instance may be compared with that during which it is heard by the examiner. For example, at the moment that the patient no longer hears the sound through bone, the fork is placed upon the mastoid process of the examiner; or after the patient ceases to hear the fork through air it is brought to the examiner's auditory meatus. In both forms of the test the length of time during which the examiner hears the sound after it is inaudible to the patient gives a measure of the hearing loss. A patient with middle ear deafness hears the sound by bone-conduction for a longer time than the examiner, in whose ear the tone of the fork is masked by room noise. In a perfectly silent room, of course, the patient's hearing through bone would be no better than the examiner's. In perceptive deafness the tone is heard through bone for a shorter time than the normal.

TESTS OF AUDITORY ACUITY. The foregoing tests are employed in determining the part of the auditory apparatus affected. Other test sounds, such as the observer's voice (whisper), the click of a coin or the tick of a watch, are used in determining the threshold of hearing. Since a sound varies inversely as the square of the distance from its source, these tests have no meaning unless the maximum distance at which the sound can be heard by the subject is known and compared with that which can be heard by the average normal ear. The subject's hearing is then expressed as a fraction of the normal—the maximum distance at which the sound is just audible to the patient over that at which it is heard by a person with average hearing under the same conditions. In quiet surroundings a good watch is heard by the normal ear at a distance of about 3 feet and words spoken in an ordinary whisper at about 30 feet. These tests are admittedly rough and give little information of the threshold of hearing at different pitches. In such a determination a series of tuning-forks may be used. The test fork is given a “standard” blow and then held as close to the ear as possible with the flat surface facing the meatus. The time, t , in seconds from the moment that the blow is struck until the sound becomes inaudible to the patient,

is compared with the normal time, t_0 . The degree of hearing loss is then derived from the difference, $t_0 - t$.

The audiometer. Within recent years an instrument known as the *audiometer* has been introduced for the rapid and more precise testing of auditory function. The apparatus is designed upon principles similar to those used in radio sets, the test tones being generated electrically and conveyed by wires to a receiver applied to the patient's ear. The tone is varied in intensity or pitch as required by means of dials upon the front of the instrument. The intensity (in decibels above the audible threshold) or the pitch is indicated directly on the respective dial. In one form of the instrument compound tones covering the range of speech frequencies are employed; another type replaces the tuning-fork test, a series of pure tones with frequencies ranging from 64 c.p.s. to 8000 c.p.s. being employed. In a third type speech sounds from a gramophone record are led through the instrument and then to a receiver applied to the patient's ear. The results of the test are plotted as shown in fig. 491. Such a record is called an *audiogram*. Special receivers have also been designed for bone conduction tests. Alternating electrical currents are transformed into mechanical vibrations applied to the skull.

THE HARMFUL EFFECTS OF NOISE. Noise is recognized as an annoyance and a general nuisance but is not, as a rule, classed as an influence detrimental to health or efficiency. Yet there is no question that, quite apart from the injurious effects of prolonged and loud sounds upon the internal ear (p. 1045) or of loud reports upon the ear drum and mechanism of the middle ear, noisy surroundings can lead to mental irritability, "nervous strain" and increased expenditure of energy. Noise reduces efficiency and accuracy in the performance of manual work, e.g., mail sorting, typesetting, operating factory machines, etc., which demand some degree of attention. The distracting effect of noise upon mental tasks and its interference with restful sleep are too obvious to require comment. That it has a deleterious influence upon persons seriously ill is unquestionable; it is therefore reasonable to believe that, though a healthy person appears to endure almost any degree of noise without immediate detriment to his well-being, he is not immune to its ill effects. There are many observations to the contrary. Watkyn-Thomas and Yates cite the case of an elderly office

worker who was moved from a quiet to a noisy environment. Although his disposition had previously been kindly and courteous it became altered in an unaccountable way; not until he took up his quarters again in a quiet room did his good nature return. In factory workers the accuracy of certain types of operation may be reduced by from 50 to 60 per cent by noise. In a telephone exchange wrong numbers were observed to decrease by 42 per cent when the noise was lowered

FIG. 491.

from 5 to 3.5 bels. It has also been shown that noise increases the oxygen consumption for a given piece of light work, e.g., typing, by from 20 to 25 per cent. The extra energy expenditure is due apparently to increased action of the heart, more rapid respiratory rate and greater muscular tone. In animals, e.g., cats, dogs, rabbits and frogs, such reactions, as well as a rise of blood pressure, can be shown to result from continuous noise or from a sudden loud sound. Beatty points out that there are only three things which evoke a fear reaction in very young infants, namely, letting them fall even a short distance through the air, holding their arms to their sides, or a *sudden loud noise*.

CHAPTER LXXXI

THE CHEMICAL SENSES

TASTE

Taste and smell are chemical senses, that is to say, the receptors (chemoreceptors) for these senses respond adequately to chemical stimuli. In order, therefore, for a substance to arouse a sensation of taste it must be dissolved—either taken in solution or dissolved in the saliva; a solid taken into a perfectly dry mouth is tasteless. For this reason the organs of taste or *taste buds* are present only upon a moist surface, being confined to the mouth region of all air-breathing vertebrates, but may be anywhere upon the body surface of aquatic forms.

THE ORGANS OF TASTE. The taste buds of man are mainly situated on the tongue but a few are also found in the mucous membrane covering the soft palate, fauces, epiglottis and the region of the arytenoid cartilages. Taste buds are more widely distributed in children, and are especially plentiful over the anterior part of the tongue. In the adult they are much fewer at the tip of the tongue and are almost absent from the middle third. In fishes the skin of the general body surface is plentifully supplied with taste receptors, and in the catfish and certain other species of fish they are contained in the filiform processes known as barbules projecting from the snout and angles of the mouth. In insects (flies, bees) taste receptors are located at the end of the proboscis and upon the tarsal segments of the legs.

The mucosa of the human tongue is studded with large numbers of small elevations—the *lingual papillae*—caused by projections of the corium. The papillae are of three main types, filiform, fungiform and vallate. The *filiform papillae* are very minute conical structures covering the anterior two-thirds or so of the dorsal surface of the tongue. They are arranged in rows running roughly parallel with the rows of vallate papillae. The *fungiform papillae* are considerably larger than the preceding type, round in shape and situated mainly at the tip and edges of the tongue. The *vallate papillae* are much larger and become especially prominent posteriorly where from six to twelve are arranged conspicuously in the form of a V with its limbs open anteriorly. A vallate papilla consists of a central round elevation with perpendicular sides and surrounded by a sulcus; the taste buds are situated in the mucosa forming the walls of this circular trench. The filiform papillae rarely contain taste buds, but each fungiform papilla usually holds from 8 to 10 embedded in the epithelium covering its free surface.

A section of a taste bud is shown in figure 492. It measures about 70μ long and 50μ broad, and lies with

its long axis perpendicular to the epithelial surface. It consists of groups of *supporting cells* (*peripheral supporting cells*) shaped somewhat like the sections of a musk melon and arranged side by side to enclose a small oval chamber which opens superficially through a circular gap—the *inner taste pore*—bounded by the converging ends of the supporting cells. The inner taste pore usually leads into a short canal which opens in turn through the *outer taste pore* upon the surface of the tongue. The cavity of the taste bud is occupied by other supporting cells (*central supporting cells*) in the intervals between which the taste receptors (*taste cells*) are lodged. The taste cell is spindle-shaped and provided with a fine hair-like process which projects through the inner taste pore into the short canal men-

FIG. 492. Vertical section through a taste bud.

tioned above. The taste bud contains a variable number of these sensory cells, usually from 5 to 18. Nerve fibers after losing their medullary sheaths penetrate the bud and arborize upon the surface of the taste cells.

The chief nerves of taste are the *chorda tympani* branch of the facial nerve and the *glossopharyngeal nerve* (see fig. 183, p. 418). The former supplies the taste buds over the anterior two-thirds of the tongue, the latter is distributed to the posterior third. The *vagus nerve* innervates the few taste buds which are present in the region of the epiglottis and arytenoid cartilages. The *trigeminal nerve* mediates common chemical sense (p. 1058) and sensations of touch, temperature and pressure (common sensibility) from the entire buccal mucosa; it does not contain taste fibers. Cushing observed, for example, that removal of the semilunar ganglion did not cause any permanent loss of taste (p. 858). Section of the nerves of taste in animals is followed by degeneration and gradual disappearance of the taste buds. Olmsted has shown in experiments upon the catfish that taste buds reappear upon regeneration of the nerve fibers. The latter evidently exert a formative influence, possibly

through the medium of a chemical substance, upon the development of the taste organs.

The central connections of the nerves of taste are described on pages 859-861 and 895.

THE SENSATIONS OF TASTE

There are four *simple, primary* or *fundamental* tastes—*sweet, sour (acid), salty* and *bitter*. Two others are sometimes added, namely, *alkaline* and *metallic*.¹ The various other tastes which we experience are (a) blends of two or more of the primary sensations or (b) combinations of the latter with sensations aroused by the stimulation of the nerves of common sensibility. For example, ginger is recognized not only by its taste (i.e., through impulses from the taste buds), but also by the burning sensation caused by the excitation of the ordinary sensory nerves of the mouth and also, we may add, by its odor. Many other substances, such as fats and oils and pungent condiments, are “felt” as well as tasted.

Many of the finer flavors are in reality sensations of smell, and olfaction enters very largely into many of the sensations which we generally class as tastes. For this reason when the nose is held or the nasal passages blocked, as during an ordinary cold, our sense of taste seems blunted. It may then be impossible if two foods are of the same consistency to distinguish between them; thus an apple and a pear, or a turnip and a potato, taste alike. On the other hand, certain substances which we think that we detect by smell are actually tasted. The sweetish smell of chloroform is an example; the vapor reaches the taste buds in the inspired air.

The four primary gustatory sensations are not aroused with equal intensity over all parts of the tongue. Apparently there is a functionally distinct type of receptor for each primary taste, and the distribution of each type is not uniform over the lingual mucosa. End organs sensitive to sweet and salty materials are most plentiful at the tip, those responsive to acid are distributed mainly along the margins, while those aroused by bitter substances are towards the base of the tongue and in the region of the epiglottis. These facts are recognized generally in practice, for one would no

more think of sipping beer than he would of gulping a glass of wine, and a child prefers to lick rather than munch a stick of candy. Some substances stimulate two types of taste bud. For example, *sodium salicylate, rhamnose* and *para-brom-benzoic-sulphinide*, a substance related to saccharine, give a sweet taste when applied to the tip of the tongue but when swallowed, and thus brought into contact with the vallate papillae, taste bitter. *Ortho-benzyl-benzoate*, on the other hand, gives a bitter followed by a sweet taste. *Magnesium* and *sodium sulphates* are salty-bitter, causing a salty taste at the tip of the tongue and a bitter taste at the base. When the papillae are

FIG. 493. Showing distribution of primary taste sensations on one side of the tongue.

explored individually with different sapid substances it is found that the filiform type are insensitive. Of the fungiform papillae, some respond to both sweet and salty compounds, others to acid and sweet and others again to bitter and acid. A few respond to all four types of stimulus. These results indicate the existence of functionally distinct types of taste receptors and that different types are present in the same fungiform papilla. Only taste buds responsive to bitter substances are present in the vallate papillae (fig. 493).

Gustatory impulses in single nerve fibers aroused by the application of chemicals to the tongue of the cat have been recorded by Pfaffman. Only three types of active fiber were identified, (a) those which responded to acid, (b) those which responded to acid and salt, and (c) those which responded to acid and quinine. No difference was observed in the character of the impulses which might serve to distinguish the type of stimulus employed. Such a finding is in accord with what we know of other sense organs, namely, that the quality of sensation is determined by the central connections of the nerve

¹ Opinions differ as to the nature of these two sensations, most investigators contending that the former is a compound sensation, resulting from the excitation of several types of end organs, including those for sweetness and for touch. Similarly, the metallic taste caused by the salts of heavy metals, copper, silver, mercury, etc., is believed to be a complex of sour and sweet. Some maintain indeed that it is due chiefly to the stimulation of olfactory receptors.

fiber, that is, upon the part of the brain where the impulses set up in the receptor organ by an adequate stimulus, are delivered.

The sense of taste may be aroused by substances reaching the taste buds in the blood stream. Thus the intravenous injection of histamine causes a metallic taste, glucinum a sweet taste, and in jaundice a bitter taste may be experienced as a result of the high concentrations of biliary constituents in the blood.

TASTE SENSATIONS AND CHEMICAL CONSTITUTION. The *sweet* taste is associated predominantly with organic compounds, especially the *sugars* (e.g., sucrose, maltose, glucose, etc.) certain *polysaccharides*, the *alcohols*, *aldehydes* and *ketones* of the aliphatic series, and *saccharine*, *dulcine* and *chloroform*. But certain inorganic substances, such as *lead acetate* (sugar of lead) and *alkalis* in high dilution, are also sweet to the taste.

Several attempts have been made to relate the sweet taste to chemical constitution. Oertly and Myers, for example, from a study of a large number of sweet organic compounds have proposed the theory that every sweet molecule contains two particular types of radical or an atom upon which the sweet taste depends. One of these they call a *glucophore*, the other an *auxogluc*. A glucophore makes a given compound a potential tastestuff; if it is bound to an auxogluc a sweet compound is produced. Some six glucophores and nine auxoglucs have been identified; four of each are listed in the following table.

Glucophores	Auxoglucs
(1) —CO—CHOH—(H)	(1) H
(2) $\text{CO}_2\text{H} \cdot \text{CHNH}_2\text{—}$	(2) CH_3CH_2
(3) $\text{CH}_2\text{OH} \cdot \text{CHOH—}$	(3) CH_2OH
(4) $\text{CH}_2\text{ONO}_2\text{—}$	(4) $\text{CH}_2\text{OH CHO}$

Thus the hexoses contain the glucophore (1) and the auxogluc (4), glycerol the glucophore (2) and the auxogluc (3), and amino-acetic acid the glucophore (2) and the auxogluc (1).

The *salty* taste is evoked primarily by inorganic compounds, notably the *chlorides* of *sodium*, *potassium*, *magnesium*, *ammonium* and *lithium*, by certain *sulphates*, *bromides* and *iodides* and by *sodium* and *potassium nitrates*. The saline taste of such compounds is attributed to the anions (Cl , Br , I , SO_4 and NO_3), a conclusion arrived at from a comparison of their tastes when in high dilution with that of an equally weak solution of sodium acetate. For example, a 0.04 molar solution of NaCl , of KCl or of LiCl has a slightly

salty taste, whereas sodium acetate in equal or somewhat lower dilution is tasteless or at least is not salty. Similarly sodium bromide, iodide or nitrate loses its saline taste at a much higher dilution than does the acetate. Of the halogens the dilution at which the salty taste is just perceptible is highest for the chloride, next for the bromide and lowest for the iodide ion. The saline taste is not confined to inorganic compounds. Certain organic compounds, such as the *hydrochlorides* of *monomethylamine* and *diethylamine* also possess this property.

The *sour* taste is produced by acids or acid salts. It is generally agreed that the effective agent is the hydrogen ion. This statement would seem to be contradicted by the fact that solutions of certain organic acids, such as acetic, tartaric, citric, etc., are more acid to the taste than a solution of a mineral acid having a considerably greater hydrogen ion concentration. For example, the acid taste of a solution of acetic acid is about equal to one of HCl in a dilution one third as great. Yet as compared with the latter solution, the solution of HCl , since this acid is highly dissociated, is from 4 to 5 times as great. The greater effectiveness of acetic acid for a given H ion concentration is attributed to its greater power of penetrating the tissues, and therefore to its greater effectiveness in raising the hydrogen ion concentration within the taste buds. The *astringent* taste is attributed to acid in very high dilution, that is, to a greatly attenuated sensation of sourness.

The *bitter* taste, like sweetness, is associated chiefly with organic compounds, especially the *alkaloids* (*quinine*, *strychnine*, *morphine*, etc.) and certain *glucosides*. *Picric acid*, *dextromanose* and *bile salts* are among the other bitter organic compounds. Of inorganic substances with a bitter taste are *magnesium*, *ammonium*, and *calcium salts*. The bitterness of these salts is due to the cation. A slight change in the chemical constitution of a substance often alters its taste from bitter to sweet. Saccharine, for example, is intensely sweet, but some of its derivatives are bitter; dulcin is some 500 times sweeter than cane sugar yet *phenyl-thio-carbamide*, in which one oxygen atom in the dulcin molecule is replaced by a sulphur atom, is bitter to most persons. Phenyl-thio-carbamide is peculiar in that to 3 persons out of 10 it is tasteless. The taste deficiency ("taste blindness") in respect to this substance is hereditary, being transmitted as a Mendelian recessive.

Many organic compounds having a bitter taste contain NO_2 groups. If the molecule contains two such groups the compound is usually, though not necessarily, bitter; if three are present it is invariably so.

INADEQUATE STIMULI. Of agents other than chemical which are capable of evoking a sensation of taste by far the most effective is the electrical current. Electrical stimulation by means of the constant current, using a pair of electrodes placed upon the tongue causes, upon breaking the current, a metallic taste which persists for a little time. If one electrode is placed in contact with the surface of the tongue and the other upon some indifferent part of the body, a constant current during its passage causes an acid or alkaline taste, depending upon the direction of the current. If the lingual electrode is the anode an acid taste is experienced, whereas if the cathode is the stimulating electrode the taste is alkaline. Two factors, apparently, are concerned in the production of the acid or alkaline taste, namely, direct electrical stimulation of the taste cells and the production of H and OH ions at the anode and cathode, respectively, as a result of electrolysis of the buccal fluids. That a gustatory response can be produced by direct electrical stimulation is evident from the fact that it is more readily aroused by a rapidly alternating current, which has no appreciable electrolytic action, than by a direct current. Furthermore, when two persons are connected each to a pole of a battery and the circuit completed by bringing the tips of their tongues together, they experience different taste sensations, one acid the other alkaline. Now the two sets of taste buds must be exposed to the action of the same ions, the only condition of the experiment which is different in respect to the taste organs of the two persons is the direction of the current. The electrical taste evoked by a constant current is a rather complex sensation and cannot be described as purely acid or alkaline in quality. It frequently has a bitter metallic component which, as mentioned above, is usually the only taste caused by a single break shock. Very probably electrolytic products as well as the direct stimulating effect of the current are responsible for evoking the complex response. The gustatory sensation caused by a single shock is apparently due purely to direct electrical stimulation, since a current of such brief duration could not have any electrolytic action.

Thermal and mechanical types of stimulation may arouse faint sensations of taste but, as a rule, are ineffective.

Thresholds of the primary taste sensations. Minimum concentrations of the four main groups of sapid substances which will evoke the corresponding sensations are given in the following table.

<i>Sensation and substance</i>	<i>Concentration</i>
<i>Sweet</i> cane sugar.....	1 part in 200
dulcin.....	1 part in 100,200
α -antialdoxine	
perillaldehyde.....	1 part in 600,000
<i>Salty</i> , sodium chloride.....	1 part in 400
<i>Acid</i> , hydrochloric.....	1 part in 15,000
<i>Bitter</i> , quinine.....	1 part in 2,000,000
strychnine.....	1 part in 2,500,000

AFTER TASTE AND TASTE CONTRASTS. The sense of taste exhibits phenomena analogous to positive after images and successive and simultaneous contrast, which have been described for vision (p. 982). It is a familiar experience that the tastes of certain substances (e.g., quinine) "cling" to the tongue. But it is unlikely that the persistent taste is a true after sensation comparable with an after image; it is most probably due simply to the continued action of the stimulating agent which, having entered the taste pore, is removed with difficulty by the saliva or even by rinsing the mouth with water. On the contrary, the metallic taste which outlasts a single break shock is in all likelihood an example of the persistence of sensation.

Several observations exemplifying *successive contrast* can be cited. A sweet taste is enhanced by a preceding salt or bitter taste and vice versa. In the same way sour and sweet tastes intensify one another. Even distilled water tastes sweet after rinsing the mouth with a weak solution of sulphuric acid, and lemon juice seems much more acid following a sweet stimulus. Other examples which should probably be placed under the heading of successive contrast are the sweet taste which is experienced upon smoking a cigar or cigarette after washing out the mouth with a weak solution of copper sulphate, and the bitter taste caused by smoking if the tongue or buccal mucosa has been treated with a solution of silver nitrate. *Simultaneous contrast* is also demonstrable. For example, if one border of the tongue is rubbed with salt the sensitivity of the opposite border to a sweet stimulus is increased. This contrast effect must, of course, be of cerebral origin. Salt and acid also show simultaneous contrast, but the phenomenon cannot be demonstrated for the bitter taste.

The effects of drugs upon taste. Certain drugs have a selective action upon the taste sensations, abolishing some while leaving others unaffected. For example, after the application of a decoction of the leaves of *Gymnema sylvestre* to the tongue, sweet and bitter substances cannot be tasted, but saline and acid tastes are retained, and are only slightly if at all depressed. *Stovaine* acts similarly to gymnema but is less effective. *Cocaine* abolishes all taste as well as common sensibility,

the several sensations disappearing in the following order; pain, bitter, sweet, saline, acid and touch.

SMELL

THE OLFACTORY EPITHELIUM. The mucous membrane lining the greater part of the nasal cavity has no true olfactory function (see p. 1054). The olfactory receptors are confined to the nasal mucosa over a relatively small region—the *olfactory area*. This area comprises, on each side, the walls of a narrow niche (fig. 494) formed by the superior nasal concha, the upper part of the septum and the roof of the nose (cribriform plate of the ethmoid bone). The olfactory epithelium differs both in its gross appearance and

FIG. 494. Upper, human olfactory cleft opened by turning nasal septum (S) upward; black area represents olfactory epithelium. (Redrawn from Parker, after Read.) Lower, transverse section through human left nasal cavity. 1, olfactory cleft, 2, septum; 3, 4 and 5, superior, middle and inferior conchae.

histologically from the rest of the nasal mucosa. It is yellowish or brownish yellow in color; its total area, i.e., on both sides of the nose, is about 500 square millimeters.²

² The *vomero-nasal organ* (organ of Jacobson) is a short tubular structure which, though well developed in certain lower vertebrates, is rudimentary in primates. It can be identified in a vestigial form in infants but, though it may persist throughout life, it is commonly absent in the adult. When present it is situated in the lower anterior part of the nasal septum and opens into the cavity of the nose by a minute pore a short distance within the external nares. In the dog and cat it receives both olfactory and trigeminal fibers and contains epithelium similar to that of the olfactory area. The function of the vomero-nasal organ is not known with certainty but its general structure and innervation suggest very strongly that it is a subsidiary olfactory sense organ.

The olfactory epithelium is composed of three types of cell (a) supporting cells, (b) basal cells and (c) bipolar nerve cells. The *supporting cells* are of a very high columnar type with large oval nuclei. Superficially, they form a continuous epithelial surface, except for small round gaps between them through which the olfactory vesicles with their tufts of hairs project (see below). Their cytoplasm contains granules of a golden brown pigment to which the color of the olfactory epithelium is due. Proximally, the supporting cell tapers into a long slender process which extends as far as the lamina propria (fig. 495, A). The *basal cells* are squat conical structures which extend for only a short distance above the lamina propria. They are believed to develop into supporting cells, thus serving as a reserve from which the latter when destroyed can be replaced.

The *bipolar nerve cells* are the essential olfactory sense organs. Their two processes arise from opposite poles of the fusiform cell body, the dendrite from its superficial and the axon from its deep aspect. The dendrite is a long straight and relatively stout cylindrical process. It extends to the epithelial surface and projecting through one of the gaps between the supporting cells, expands slightly to form the *olfactory vesicle*. The latter contains from 6 to 8 granules each of which gives rise to a hairlike protoplasmic process. The axon of the bipolar cell proceeds centrally from the deep aspect of the perikaryon and after traversing the lamina propria, joins with the central processes of neighboring cells to form some 20 nerve strands—the *fila olfactoria* or *olfactory nerves*. The latter ascend in grooves in the ethmoid bone and, entering the skull through perforations in the cribriform plate of this bone, end within the *olfactory lobe (bulb)* by synapsing with dendrites of the *mitral cells* and *tufted cells* (fig. 495, B). The synapses form conspicuous spherical structures called the *olfactory glomeruli*. The axons of the mitral and tufted cells constitute the *olfactory tract*. Most of the fibers of the latter are continued into the *lateral olfactory stria* which conveys the impulses to the cortical center for smell (p. 896). The olfactory nerves are non-medullated, but possess a neurilemma. The lamina propria of the olfactory mucous membrane contains glands of the tubulo-alveolar type—the *glands of Bowman*. They secrete a serous fluid which bathes the epithelial surface, thus providing a solvent for odorous materials. The fluid is delivered by fine ducts which take a perpendicular course to the surface.

It will at once be recognized from the foregoing description that the end organs of smell differ from those of any other sense in that the cell body of the primary neuron is situated in the peripheral organ itself, and is stimulated directly without the intervention of a specialized receptor cell. No other sensory mechanism possesses both these features. Though the primary neuron of the visual pathway is situated in the retina, the stimulus is received by the rods and cones:

pain sensations are subserved by bare nerve endings, the cell bodies of the pain fibers are located in the posterior root ganglia. It is also important to remem-

FIG. 495. A, cells from olfactory mucous membrane separated from one another and highly magnified. 1, olfactory receptors; 2, supporting cells. B, central connections of the olfactory nerves. 3, cells of olfactory mucous membrane; 4, olfactory nerve fibers piercing the floor of the skull to reach the olfactory bulb; 5, connections of olfactory nerves with processes of mitral cells in olfactory bulb; 6, mitral cells; 7, fibers passing into the olfactory tract.

of fluid. Furthermore, the sheaths of the olfactory nerves are continuous with the subarachnoid space. Experimental work indicates that the olfactory nerves constitute one pathway through which the virus of anterior poliomyelitis reaches the central nervous system. Shultz and Gebhardt have shown, for example, that monkeys are protected against the intranasal injection of poliomyelitis virus by a previous section of the olfactory nerves. Intranasal sprays, consisting of solutions of zinc sulphate and other substances have been employed in monkeys with the purpose of blocking these channels. The encouragement derived from the success of these experiments in protecting animals from the disease has led to the trial of similar measures in poliomyelitis epidemics, but unfortunately they do not appear to have any value in reducing the number of cases. It is very difficult, especially in children, to bring the solution into contact with the olfactory epithelium, and this is probably the reason that reliance cannot be placed upon intranasal spraying as a preventive. The recent experiments of C. G. Smith are enlightening. The olfactory areas of rats were treated with a 1 per cent solution of zinc sulphate and examined histologically at periods of from 2 days to 2 months thereafter. In animals so treated, destructive changes amounting even to sloughing of the entire olfactory epithelium were found, and in all cases the bipolar cells showed widespread degeneration. Regeneration of non-sensory cells (supporting and basal) subsequently occurred, but, of course, the nerve cells were not restored. It would appear from these experiments that zinc sulphate solution, if it is to be effective in protecting the intestinal pathway against the virus of poliomyelitis, must entail permanent loss of the sense of smell.

THE PHYSIOLOGY OF THE SENSE OF SMELL

OLFACTORY SENSATIONS. Smell is very closely allied to taste and has been aptly described as "taste at a distance." In many animals the sense of smell is almost incredibly acute, a relatively large part of the brain being given over to it. In the life of such macrosmatic animals the olfactory sense is of paramount importance, warning the animal of the approach of its enemies, guiding it in the quest for food and motivating the sex reflexes. Certain species of moth (e.g., great peacock and banded monk) are credited with a degree of olfactory acuity which seems almost mythical to microsmatic man, the female being able, it is claimed, to attract the male by the odor of its secretions from a distance of a mile or more. The olfactory organs of moths and most other insects are located in the antennae. Even man, in whom smell is a comparatively rudimentary sense, can detect certain substances (e.g., mer-

ber that here as nowhere else the nervous system is in direct contact with the external environment. The terminations of the dendrites of the olfactory cells, namely, the olfactory hairs, are covered only by a layer

captan and artificial musk) in a dilution of 1 part in several billion parts of air; smell is therefore much more acute than the sense of taste.

The adequate stimulus for the olfactory receptors, as for those of taste, is chemical.¹ An odorous material continuously emits particles of molecular size which reach the olfactory area through the air. Substances which pass readily into the gaseous state, such as turpentine, gasoline, the essential oils, etc., have strong odors, whereas non-volatile materials, e.g., the heavy metals, are inodorous. Arsenic, which ordinarily is odorless gives off a characteristic smell, however, when heated to a temperature at which it volatilizes, and Elsberg, Brewer and Levy found that the olfactory coefficients (p. 1056) of a number of odorous liquids vary directly with their boiling points. The niche forming the roof of the nose and which is lined by the olfactory epithelium, constitutes a blind pocket, from which the main air currents caused by the respiratory movements are excluded. Experiments upon the human cadaver have shown that the respired air does not come into direct contact with the olfactory area. A head was bisected in the median plane and the nasal septum replaced by glass. When smoke was forced back and forth through the nose by means of bellows, neither during the artificial inspiratory nor expiratory movement was the current observed to enter the olfactory region. The air flow takes a curved course, the highest point being about the middle of the nose and below the superior concha. The stream reaches a lower level during expiration than in inspiration. In order to excite the olfactory cells the odorous particles must, therefore, be carried upwards from the respiratory passages either by diffusion or by eddy currents. In the aforementioned experiment eddy currents were observed both during the inspiratory and expiratory movements. In the living subject it is probable that the ascending currents are more pronounced during inspiration; at this time air movements caused by convection are likely to occur, due to the mixing of the cooler ingoing stream with the warmer air within the nose. But, however produced, whether by convection or simply as a result of the mechanical mixing of the inspired air with that within the nasal passages, eddy currents constitute the main factor

in the stimulation of the olfactory endings, and a sharp inspiration is the most effective means by which such currents are set up. When, for example, we wish to smell some particular scent more acutely we automatically make a sharp inspiration or "sniff." Diffusion is a relatively slow process and is probably of minor importance in bringing the odorous material to the olfactory endings. Even though the nose is filled with odor-laden air we cannot smell while the breath is held. It is during expiration that odorous material liberated from the food as it is masticated and swallowed enter the nose through the posterior nares and ascend to the olfactory area.

It will be recalled that the olfactory hairs are immersed in a layer of fluid secreted by Bowman's glands. The odorous particles must therefore enter into solution before they can come into contact with and stimulate the sense organ. This fact emphasizes again the similarity between the senses of taste and smell. It is probable that odorous materials before they can act as stimulus must also be dissolved in the substance of the olfactory hairs themselves. These structures, since they are stained best by osmic acid, are believed to be composed largely of lipid material. One would expect, therefore, that odorous substances must be soluble in oil as well as in water, and that those which are most freely soluble in both media would be the most potent in arousing an olfactory sensation. This supposition is borne out to some extent by experiment. Ethyl and methyl alcohols, for example, which are freely soluble in water but only slightly in oil, have weak odors as compared with butyl alcohol which dissolves very freely in oil and is also soluble in water. Chloroform, benzol, brombenzol, ether, citral and many other substances with strong odors are soluble in both water and oil. It would appear that high solubility in oil is of more importance for olfactory stimulation than high water solubility; for taking two substances, one with a high solubility in oil but sparingly soluble in water, and the other possessing solubilities of a converse kind, the former has the most powerful odor.

Though it is no longer questioned that the olfactory nerves subserve the sense of smell, some of the earlier investigators (e.g., Magendie) contended that olfaction was a function of the trigeminal nerve. The confusion arose from the fact that certain agents, e.g., ammonia, nitric acid fumes, chlorine, pepper, menthol, peppermint and many others, cause nasal sensations, usually described as pungent, acrid, irritating or cooling.

¹ An electric current acts as an inadequate stimulus. When the nose is filled with normal saline and a constant current passed through the solution an odor which is difficult to describe is experienced upon opening or closing the current.

These are not true olfactory sensations but are due to the stimulation of the trigeminal, which is the nerve mediating chemical sense and common sensibility in the respiratory part of the nasal mucosa. It is often very difficult, however, to dissociate these sensations from smell when the two types of ending are stimulated concurrently. A similar confusion arises, as already mentioned (p. 1049), in the case of taste.

Strong reflex effects, e.g., sneezing, lacrymation, respiratory inhibition, vasomotor reactions, etc., result from irritation of the trigeminal endings, whereas reflexes initiated from the olfactory receptors are as a rule mild in character, and in man are concerned mainly with salivary and gastric secretion. In animals olfactory reflexes play their most important rôle in the reactions of sex and in self preservation—the search for food and protection from enemies. Olfaction is paramount among the senses in its power to awaken a train of associations in consciousness. Everyone is familiar with strange reminiscent aura of past events which is aroused by certain familiar scents (see p. 896).

THRESHOLD STIMULI. Among the most effective olfactory stimuli are *artificial musk, mercaptan, butyric acid, iodoform* and *oil of peppermint*. For example, methyl mercaptan (garlic odor) is perceptible to the average person in a concentration of 1/23,000,000,000 of a milligram per cu. cm. of air. Assuming that 50 cc. of air is required for arousing an olfactory sensation, this would mean that 1/460,000,000 mgm. of the substance is an effective stimulus. The sense of smell is therefore many thousand times (about 1,000 times in the case of ethyl alcohol) more acute than the sense of taste. The minimum perceptible concentrations of various odorous substances are given in the following table.

Substance	Mgm. per liter of air
Ethyl ether.....	5.83
Chloroform	3.30
Pyridine.....	0.032
Oil of peppermint.....	0.024
Iodoform.....	0.018
Butyric acid.....	0.009
Propyl mercaptan.....	0.006
Artificial musk.....	0.00004

(from Allison and Katz)

SENSORY ADAPTATION. The olfactory receptors adapt fairly rapidly. It is a common experience that a disagreeable odor which when first smelt is almost overpowering soon becomes imperceptible. But although lost for one particular odor the sense of smell

is retained for others; the phenomenon therefore is not due to fatigue of the olfactory mechanism,⁴ but is an example of sensory adaptation (p. 806). The rate of adaptation varies for different odors. The receptors become insensitive to oil of orange or to oil of lemon after an exposure of from 2.5 to 11 minutes (average 3 minutes), whereas cumarin (0.2 per cent aqueous solution) cannot be smelt for longer than from 1.75 to 2.3 minutes, and adaptation for the odor of benzoin is more rapid than for that of rubber.

Olfactory adaptation commences to develop from the moment that the odor is first smelt, the threshold rising gradually until complete insensitivity to that particular odor is reached. Even a previous period of exposure to a given odor raises the minimum concentration at which it is perceived for a considerable length of time afterwards. Elsberg found, for example, that the olfactory coefficients (p. 1056) for peppermint, camphor and sassafras were increased to double their normal values if the subject had previously been smelling these substances; and the sensitivity of a person who had been for a time in the operating theater to the odor of ether was below normal several hours later.

CHEMICAL CONSTITUTION IN RELATION TO OLFACTORY STIMULATION. Generally speaking, the olfactory potency of chemical compounds belonging to an homologous series increases progressively from the lowest members of the series to the highest. The odors of the monatomic alcohols, for example, increase in strength from methyl through ethyl, propyl and butyl to amyl; the relative potencies of methyl and amyl alcohols are as 1 to 10,000. Also, compounds which as a group resemble one another in their chemical and physical properties tend to have odors possessing certain common characteristics. For example, the elements sulphur, selenium and tellurium, which belong to the sixth group in Mendeljeff's periodic table, when combined with hydrogen, methyl or ethyl, etc., have strong disagreeable smells. Similarly members of the seventh group, chlorine, bromine and iodine have kindred odors; the odors of chloroform and iodoform, compounds of the first and third elements respectively, are linked together by that of bromoform in which the fragrance of chloroform and the unpleasant odor of iodoform can be detected. Of chemically allied organic substances, ethyl, propyl and butyl acetates have an acetic odor, whereas amyl acetate has not, nevertheless the smell of the lowest of the series is linked with that of the highest through the two intermediate compounds. Thus—

Ethyl acetate, acetic odor

Propyl acetate, acetic odor with slight pineapple flavor

Butyl acetate, slight acetic odor with pineapple flavor

Amyl acetate, no acetic odor, strong pineapple flavor

⁴ Though it is often referred to as such.

Though the foregoing are interesting examples of chemico-olfactory correlation, it is not possible to make anything more than broad generalizations in respect to chemical structure and smell, for compounds which closely resemble one another chemically may have quite different odors and others which show little resemblance in their chemical or physical properties (e.g., hydrocyanic acid and nitrobenzine, garlic and certain arsenical compounds, and artificial and natural musk) may smell very much alike. An attempt has been made in the case of aromatic compounds to relate odor to a particular radical on the benzene ring. Hydroxyl, aldehyde, ketone, ester, nitro and nitril grouping—the so-called *osmophoric groups*—have been suggested as determining the character of the odor; it is believed, however, that the latter is dependent not so much upon which particular radical is present as upon the position which any one of them occupies in the benzene ring.

FIG. 496. Diagram of Zwaardemaker's olfactometer. See text.

OLFACTOMETRY. The most widely known method of investigating the sense of smell is that of Zwaardemaker. His olfactometer consists of two tubes sliding one inside the other, as illustrated in figure 496. The inner tube is made of glass and graduated in sections 0.7 cm. long. The outer tube, also of glass, has a lining of indiarubber, beeswax, sealing wax or some other faintly odorous material. The curved end of the inner tube is introduced into a nostril, the opposite one being closed; the subject breathes quietly. The outer tube is gradually withdrawn, thus exposing a greater area of its inner surface to the air current and thereby increasing the concentration of the odorous particles in the inspired air. The highest figure visible on the inner graduated tube when the odor is just perceived indicates the subject's threshold for smell in units termed *olfacties*. This method gives at the best only approximate results, chiefly because the volume of inspired air drawn through the tubing varies considerably from subject to subject and in the same person at different times or even during a single period of observation. In the *blast method* of Elsberg and Levy this factor is controlled. Thirty cubic centimeters of an odorous liquid (e.g., benzene citral, oil of orange, oil of turpentine, butyric

acid, etc.) are placed in the bottle shown in figure 497. The right hand tube is connected to a double nosepiece which fits into the nostrils. By means of a syringe connected to the other tube a measured volume of air is forced from the bottle in one blast at a constant pressure while the subject holds his breath. An equivalent volume of odor-laden air is thus forced into the nose. The volume of the injections is gradually increased in successive blasts until the odor is just perceived and can be named. The smallest volume necessary for identification is called the *minimum identifiable odor* (M. I. O.) or the *olfactory coefficient*.

This method has been employed by Elsberg as an aid in the localization of tumors in the anterior fossa of the skull. In this situation a tumor (e.g., of the

FIG. 497. Illustrating the blast method of olfactometry. (After Elsberg and Levy.)

frontal lobe) is likely, through direct pressure, to involve the olfactory lobe or tract of one or of both sides; or the olfactory nerves may be torn in fractures through the cribriform plate. Unilateral involvement of the olfactory nerves, lobe or tract raises the M.I.O. or completely abolishes the sense of smell on the affected side. A tumor involving both olfactory lobes or tracts will result in lowered acuity of smell or complete anosmia on both sides. Elsberg states that tests for olfactory "fatigue" give valuable localizing aid; the "fatigue" phenomenon is prolonged beyond the normal limits by tumors within the substance of the temporal lobe, but not by those situated extracerebrally (e.g., beneath the frontal lobe). In cases of a generalized increase of intracranial pressure due to other causes the M.I.O. is often lowered.

CLASSIFICATION OF ODORS. The division of odors into categories has proved an extremely difficult problem. There are no basic qualities of olfaction comparable to sweet, salty, sour and bitter tastes. The number of different and distinct smells is legion, and no comprehensive classi-

fication upon the basis of chemical constitution or physical properties can be even attempted. The earliest classification of odors was made by the Swedish botanist Linnaeus (1750). The following one proposed by Zwaardemaker, which is little more than an elaboration of that proposed by Linnaeus, consists of nine categories. It has a purely subjective basis and is therefore of little scientific value.

1. *Ethereal odors*; e.g., of fruits, beeswax, ethers.
2. *Aromatic or resinous odors*; e.g., of camphor, bitter almonds, cloves, lavender.
3. *Fragrant or balsamic odors*; e.g., of flowers, extracted or artificial perfumes.
4. *Ambrosial odors*; e.g., of musk, ambergris.
5. *Garlic odors*; e.g., of garlic, onions and of sulphur and selenium compounds.
6. *Burning odors*; e.g., of burning feathers, tobacco, roasted coffee and meats.
7. *Goat odors*; e.g., caproic acid, sweat and ripe cheese.
8. *Repulsive odors*; e.g., of hyoscyamus and several of the family of the deadly nightshade, bedbug.
9. *Nauseating odors*; e.g., of excrement, decaying meat and vegetable matter.

ACTION POTENTIALS FROM THE OLFATORY PATHWAYS. Gerard and Young have recorded the action currents from the olfactory bulb of the frog. A spontaneous rhythmical discharge occurs in this part of the isolated brain at the rate of about 4 per second. The discharge is taken as representing true automatic activity of the nerve cells of the bulb itself, for the possibility that it was due to the irritation of traumatized structures seems to have been excluded.

In certain fishes (catfish, carp and tench) the olfactory bulb is connected with the forebrain by a nerve strand (the *olfactory stalk*) which measures about 2 cm. long and is composed of from 500 to 1000 medullated fibers. Adrian and Ludwig studied the action potentials in the olfactory stalk of the catfish during stimulation of the olfactory end organs. The latter are contained in a small sac which opens through a nipple upon the surface of the skin above the mouth. Potential changes of small amplitude pass up the stalk as long as the preparation survives, though nothing but distilled water has been introduced into the sac. This *resting discharge* is of very low frequency. When the sac was irrigated with fluid containing small fragments of some odorous material, e.g., putrefying earthworms, a burst of impulses occurred at high frequency after a latent period of from 0.5 to 5 seconds or longer. It was found that the irrigation was more powerfully stimulating if the fluid contained small fragments of the material than if it had been filtered. The nervous discharge is not rhythmical, there being no evidence that groups of fibers discharged synchronously. Mechanical stimulation, caused by pressing upon the roof of the sac or by touching its interior with a brush, was also found effective.

THE QUESTION OF OLFATORY DISCRIMINATION. The great multitude of distinguishable odors brings up a question for which no answer is forthcoming, namely, "What is the mechanism underlying olfactory differentiation?" "How do we detect the difference between two scents such as those of the violet and the rose?" Or, to make the question still more difficult, "How does a dog recognize the smell of his master among the smells of other persons?" Were there a limited number of basic odors, as there are fundamental tastes, the problem would not be difficult, but such are unknown. For vision we can postulate three types of receptor, each responsive to a particular set of wave lengths, and each discharging impulses along a specific nerve fiber to the brain (see doctrine of specific nerve energies (p. 808). A place theory (p. 1041) is capable of accounting for pitch discrimination, and four functionally distinct types of taste bud, each with its specific nerve fiber, for the perception of the fundamental sensations of taste. But it is not conceivably possible that every one of the immense number of different odors is subserved by a specific type of end organ with its own nerve fiber. Furthermore, new and distinct odors are being created in industry every day. From what we know of other senses we can presume that the *intensity* of the olfactory sensation is related to the frequency of the impulses discharged to the olfactory center. This is borne out by the experiments of Adrian and Ludwig just described. But no satisfactory theory has been proposed to explain the different qualities of the olfactory sense.

THE EFFECT OF ONE ODOR UPON THE PERCEPTION OF ANOTHER. Strong odors tend to mask weaker ones. If two scents are of about equal strength a blend of the two is smelt or both are identified; but if one is considerably stronger than the other it alone, as a rule, is smelt. On the other hand, certain pairs of odors in appropriate relative concentrations are antagonistic, and when the two are sniffed together both are diminished. Iodoform, for example, is antagonized by balsam of Peru, musk by bitter almonds and ammonia by acetic acid. Other pairs of neutralizing odors are cedarwood and rubber, beeswax and balsam of Tolu, benzoin and rubber, and camphor and eau de Cologne. Though the neutralizing effect may in some cases be simply chemical or physical in nature, in others there seems to be a true physiological antagonism, for the phenomenon is observed when mixing is avoided by leading the two odors directly one to each nostril.

ANOMALIES OF OLFACTION. Loss of the sense of smell or *anosmia* is not infrequent as a temporary condition, e.g., as a result of inflammation of the nasal mucosa or of the local application of cocaine or adrenaline. Complete and permanent anosmia is rare in otherwise normal persons and is usually due to absence of the olfactory bulb or olfactory nerves, but bilateral or unilateral olfactory deficiencies are frequently associated with lesions in the region of the olfactory lobes (p. 1052). Albinos are said to be anosmic, which suggests that the pigment in the supporting cells of the olfactory epithelium, which possibly serves an essential function, is lacking. Inability to smell certain odors is not uncommon. Some persons, for example, cannot smell hydrocyanic acid; the odor of mignonette, benzoin, methyl alcohol or vanillin cannot be smelt by others. Even such a strong, disagreeable smell as that of a rotten egg or of feces, may not be sensed. Partial anosmia for all scents may result from excessive smoking. *Hyperosmia* is not unusual in hysteria, in certain cerebral diseases, in raised intracranial pressure and during the initial stage of the action of cocaine. Olfactory hallucinations may occur in lesions of the temporal lobe (p. 896). In cerebral tumors, especially of the frontal or temporal lobes, an odorous material introduced into one nostril may be referred to the other. This phenomenon, known as *olfactory alloesthesia*, is analogous to *allocheiria* mentioned on page 800.

COMMON CHEMICAL SENSE

The general body surface of fishes and many other aquatic forms is sensitive to various types of chemical irritant, as are also the moist skins of amphibians. The elicitation of reflex responses from the foot of a pithed frog stimulated by a weak solution of sulphuric acid is a well known laboratory exercise. In man the common chemical sense is restricted to surfaces which are kept constantly moist, namely, the buccal and nasal mucous membranes, the conjunctivae and the mucosa of the anal canal. The common chemical sense of the first three is subserved by the trigeminal nerve, that of the anal canal by the pudendal nerve. It has already been pointed out (p. 1049 and p. 1054) that the sense organs subserving this sense in the mouth and nose are distinct from the gustatory and olfactory endings, and apparently they are not identical with those subserving pain, for dissociation of chemical and pain sensations can be effected by cocaine, the latter being abolished before the former. Thus, after the application of a 1 per cent solution of the anesthetic to the foot of the frog no response is given to pinching, pricking or scratching, while reactions to chemical agents can for a time be elicited.

SECTION IX

CHAPTER LXXIV

THE PHYSIOLOGY OF VISION. STRUCTURE OF THE EYEBALL. DUPLICITY THEORY. REACTIONS OF THE RETINA; SUBJECTIVE PHENOMENA

- ADLER, F. H. *Arch. Ophthal.*, 1934, **11**, 6.
- ADRIAN, E. D. *Nature*, 1944, **154**, 361.
- BOURGUIGNON, G., COURLAND, M. and DÉJEAN, R. *Compt. rend. Soc. biol.*, 1926, **94**, 753.
- CRAIK, K. J. W. *J. Physiol.*, 1938, **92**, 406.
- GRAHAM, C. H. and RIGGS, L. A. *J. Gen. Psychol.*, 1935, **12**, 279.
- HARTRIDGE, H. *J. Physiol.*, 1922, **57**, 52.
- HECHT, S. and VERRY, C. D. *J. Gen. Physiol.*, 1933, **17**, 251.
- RIDLEY, F. *Brit. J. Exp. Path.*, 1930, **11**, 217.
- VERRY, C. D. *Compt. rend. Soc. biol.*, 1925, **92**, 742.
- WILCOX, W. W. and PURDY, D. M. *Brit. J. Psychol.*, 1933, **23**, 233.
- ADRIAN, E. D. and MATTHEWS, R. *J. Physiol.*, 1927, **63**, 378. *Ibid.*, **64**, 279. *Ibid.*, 1928, **65**, 273.
- ANDERSON, E. E. and WEYMOUTH, F. W. *Am. J. Physiol.*, 1923, **64**, 561.
- CHAFFEE, E. L., BOVIE, W. T. and HAMPSON, A. *J. Opt. Soc. America*, 1923, **7**, 1.
- CHASE, A. M. *Science*, 1938, **87**, 238.
- DARTNALL, H. J. A. and GOODEVE, C. F. *Nature*, 1937, **139**, 409.
- DEWAR, J. and MCKENDRICK, J. G. *Trans. Roy. Soc. Edin.*, 1873, p. 141.
- EINTHOVEN, W. and JOLLY, W. A. *Quart. J. Exp. Physiol.*, 1908, **1**, 373.
- GRANIT, R. and DAVIS, W. A. *Am. J. Physiol.*, 1930, **95**, 211.
- GRANIT, R. and RIDDELL, L. A. *J. Physiol.*, 1934, **81**, 1.
- HARTLINE, H. K. *Am. J. Physiol.*, 1925, **73**, 600. *Ibid.*, 1935, **113**, 59.
- HECHT, S. *J. Gen. Physiol.*, 1918, **1**, 657. *Ibid.*, 1919, **2**, 229.
- HECHT, S., CHASE, A. M. and SHLAER, S. *Science*, 1937, **85**, 567.
- HECHT, S. and PICKELS, E. G. *Proc. Nat. Acad. Sci.*, 1938, **24**, 172.
- HECHT, S. and WILLIAMS, R. E. *J. Gen. Physiol.*, 1922, **5**, 1.
- HOLMGREN, G. *Centralbl. f. Med. Wiss.*, 1871, p. 423 (cited by Waller).
- HOLMES, G. and PATON, L. *Brain*, 1910, **33**, 389.

Monographs and Reviews

- ADAMS, D. Dark adaptation; a review of the literature. *Med. Res. Coun.*, London, Spec. Rep. No. 127, 1929.
- ADLER, F. H. Clinical physiology of the eye. Macmillan, New York 1933.

- KRAUSE, A. C. and SIDWELL, A. E. *Am. J. Physiol.*, 1938, **121**, 215.
 LYTHGOE, R. J. *J. Physiol.*, 1937, **89**, 331.
 WALD, G. *Nature*, 1933, **132**, 1316. *Ibid.*, 1934, **134**, 65. *J. Gen. Physiol.*, 1935, **19**, 351, 781. *Ibid.*, 1936, **20**, 45.
 WALLER, A. D. *Quart. J. Exp. Physiol.*, 1909, **2**, 169.

Monographs and Reviews

- DUKE-ELDER, W. S. *Text book of ophthalmology*. Kimpton, London, 1932.
 HECHT, S. The nature of the photoreceptor process; in Murchison's *Handbook of General Experimental Psychology*. Clarke Univ. Press, Worcester, 1934, p. 704.
 HOUSTON, R. A. *Vision and colour vision*. Longmans, London, 1932.
 KLUVER, H., editor. *Visual mechanisms, Biological symposia, III*, 1942, Jaques Cattell Press, Lancaster, Pa.
 PARSONS, J. H. *An introduction to the theory of perception*. Cambridge University Press, 1927.
 ROAF, H. E. *Colour vision*. *Physiol. Rev.*, 1933, **13**, 43.
 WRIGHT, W. D. and GRANIT, R. On the correlation of some sensory and physiological phenomena of vision. *Brit. J. Ophthalm.*, 1938, *Monograph Supp.* IX.

CHAPTER LXXVI

THE DIOPTRIC MECHANISMS OF THE EYE. CATARACT. OPTICAL DEFECTS. INTRA-OCULAR FLUIDS

- BENHAM, G. H., DUKE-ELDER, W. S. and HODGSON, T. H. *J. Physiol.*, 1928, **92**, 355.
 BURGE, W. E. *Am. J. Physiol.*, 1915, **39**, 335.
 CLARK, J. H. *Am. J. Physiol.*, 1935, **113**, 538.
 DUKE-ELDER, W. S. Pathological effect of light on the eye. *Lancet*, 1926, **1**, 1188. *Ibid.* 1250. *Brit. J. Ophthalm.*, 1940, **24**, 421.
 FINCHAM, E. F. *Proc. Optical Conv.*, Part I, 1926, p. 454.
 FRIEDENWALD, J. S. *Arch. Path.*, 1936, **16**, 65.
 FRIEDENWALD, J. S. and PIERCE, H. F. *Arch. Ophthalm.* 1937, **17**, 477.
 FRIEDENWALD, J. S. and STIEHLER, R. D. *Arch. Ophthalm.*, 1935, **14**, 789.
 GOLDMAN, H. and HAGEN, R. *Ophthalmologica (Basel)*, 1942, **104**, 15.
 GOLDSCHMIDT, M. *Münch. med. Wochenschr.*, 1914, **61**, 657.
 HARTBRIDGE, H. and HILL, A. V. *Proc. Roy. Soc.*, 1915, **B 89**, 58.
 HODGSON, T. H. *J. Physiol.*, 1938, **94**, 118.
 HOLMES, G. and PATON, L. *Brain*, 1910, **33**, 389.
 MACDONALD, A. E. *Trans. Am. Ophthalm. Soc.*, 1931.
 SCHWALBE. *Arch. mickr. Anat.*, 1870, **6**, 1.

Monographs and Reviews

- ADAMS, D. R. *Proc. Roy. Soc.*, 1925, **B 98**, 244. *Brit. J. Ophthalm.*, 1925, **9**, 281.
 DUKE-ELDER, W. S. The nature of the intra-ocular fluids. *Brit. J. Ophthalm.*, 1927, *Monograph Supp.* III. The practice of refraction. Churchill, Lond., 1928.
 HELMHOLTZ, H. VON. *Treatise on physiological optics*. Optic. Soc. Am., 1924.
 SOUTHALL, J. P. C. *Introduction to physiological optics*. Oxford University Press, 1937.

CHAPTER LXXVII

THE VISUAL FIELDS AND PATHWAY. MOVEMENTS OF THE OCULAR MUSCLES. STEREOSCOPIC VISION

- BEATTIE, J. *J. Anat.*, 1932, **66**, 283.
 BIELSCHOWSKY, A., *Am. J. Ophthalm.*, 1938, **21**, 843.
 BROUWER, B. and ZEEMAN, W. P. C. The projection of the retina in the primary optic neuron in monkeys. *Brain*, 1926, **49**, 1.
 CUSHING, H. *Brain*, 1921, **44**, 341.
 CUSHING, H. and WALKER, G. B. *Arch. Ophthalm.*, 1912, **41**, 559.
 HOLMES, G. *Brain*.
 RANSON, S. W. and MAGOUN, H. W. *Arch. Neur. Psych.*, 1933, **30**, 1193.
 MERRITT, H. H. and MOORE, M. *Arch. Neur. Psych.*, 1933, **30**, 357.
 SCALA, N. P. and SPIEGEL, E. A. *Arch. Ophthalm.*, 1936, **15**, 195.
 WAGMAN, I. H. and associates. *Am. J. Physiol.*, 1942, **137**, 769. *Proc. Soc. Exp. Biol. Med.*, 1942 **49**, 466.

Monograph

- TRAQUAIR, H. M. *An introduction to clinical perimetry*. Kimpton, London, 1931.

CHAPTER LXXVIII

THE EAR. ANATOMICAL OUTLINE. SOUND, GENERAL PRINCIPLES

- WIGGERS, H. L. *Am. J. Physiol.*, 1937, **120**, 771.

Monographs and Reviews

- HELMHOLTZ, H. L. *Sensations of tone*. Longmans, New York, 1930.
 JEANS, J. *Science and music*. Cambridge Univ. Press, 1937.

CHAPTER LXXIX

AUDITORY SENSATIONS. THE MECHANISMS OF HEARING. THE TELEPHONE AND RESONANCE THEORIES

- BAST, T. H. and EYSTER, J. A. E. *Ann. Otol. Rhinol. Laryngol.*, 1935, **44**, 57.
 BÉKÉSY, G. VON. *Ann. d. Physik.*, 1932, **13**, 111.
 CROWE, S. J., GUILD, S. R. and POLVOGT, L. M. *Bull. Johns Hopkins Hosp.*, 1934, **54**, 315.

- DAVIS, H., DERBYSHIRE, A. J. and associates. *Am. J. Physiol.*, 1934, 107, 311.
- GALAMBOS, R. and DAVIS, H. *Proc. Fed. Am. Soc. Exp. Biol.*, 1942, 1, 27.
- GRAY, A. A. *J. Anat. Physiol.*, 1900, 34, 324.
- HALLPIKE, C. S. and RAWDON-SMITH, A. F. *Nature*, 1934, 133, 614. *J. Physiol.*, 1934, 81, 395.
- HARTRIDGE, H. *Proc. Physical Soc.*, 1936, 48, 145.
- HARTRIDGE, HALLPIKE and RAWDON-SMITH; see HALLPIKE, C. S., HARTRIDGE, H. and RAWDON-SMITH, A. F. *Proc. Roy. Soc.*, 1937, B 122, 175, and ASHCROFT, D. W., HALLPIKE, C. S. and RAWDON-SMITH, A. F. *Ibid.*, 186.
- SAUL, L. J., and DAVIS, H. *Arch. Neur. Psychiat.*, 1932, 28, 1104.
- STEVENS, S. S., DAVIS, H. and LURIE, M. H. *J. Gen. Psych.*, 1935, 13, 297.
- WALZ, E. M. and BORDLEY, J. E. *Am. J. Physiol.*, 1941, 135, 351.
- WEVER, E. G. and BRAY, C. W. *Proc. Nat. Acad. Sci.*, 1930, 16, 344. *J. Exp. Psychol.*, 1930, 13, 373.
- Monographs and Reviews*
- BEATTY, R. T. *Hearing in man and animals*. Bell, London, 1932.
- CROWE, S. J. *Investigations into the causes of deafness*. Harvey Lectures, 1931-32, p. 100.

INDEX

- abdominal reflexes, 873
- in paraplegia, 870
- in tabes, 869
- abducent nerve, 1016, 1018
- sympathetic fibers in, 936
- Abrney's law, 976
- abortion following destruction of corpus luteum 752, 759
- absorption from gastro-intestinal tract, 504
- from tissues, 26
- of cerebrospinal fluid, 933
- of intra-ocular fluid, 1004
- of sound waves, 1026
- absorption bands, of carotene, 636
- of heat, 625
- of hemoglobin, 44, 46
- of visual purple, 971, 972
- of vitamin A, 636
- absorption coefficient of carbon dioxide, 314, 337
- of gases, 314
- of oxygen, 314
- apnea, cardio-inhibitory center, and, 213
- effect of on blood vessels, 250
- in pneumonia, 365, 366
- surgical shock and, 259
- accelerator nerves of heart, 207 et seq.
- accessory nerve, 862
- acclimatization to high altitudes, 361
- accommodation of eye, 993 et seq.
 - action of drugs in, 1014
 - age and, 997
 - constriction of pupil in, 1011
 - of nerve, 783
 - time constant of, in tetany, 702
- accommodative reflex, 1011, 1013
- accommodative theory of function of ear muscles, 1021
- accoucheur's hand in tetany, 703
- acetoacetic acid, in diabetes, 574
- acetone, in diabetes, 574
- acetonitrile test of thyroid potency, 683
- acetylcholine, 252, 946 et seq.
 - action of
 - on cardiac output, 227
 - in central nervous system, 821
 - on cerebral vessels, 292
 - on coronary vessels, 279, 280
 - on gastric secretion, 438
 - on heart, 211
 - on intestinal motility, 501
 - on salivary glands, 422
 - vasodilator, 252, 946, 947
 - hypersensitivity of denervated muscle to, 866
 - liberation by electric eel, 951
 - liberation of in central nervous system, 950, 951
 - metabolism of, 951
 - nervous effects and, 946 et seq.
- cetylene method of measuring cardiac output, 229
- chalasia of cardiac sphincter, 482
- of pelvi-rectal sphincter, 508
- visceral pain and, 516
- Charcot-Tiers syndrome, 699
- chlorhydria, 442, 443
- in pernicious anemia, 64, 66, 443
- choluric jaundice, 56, 61
- reticulocytes in, 12, 56
- chondroplasia, 718
- chronic anemia, 66
- chromatic interval, 968
- chroodextrin, 421
- Achylia gastrica, 443
- Acid, acids, see also under specific names, acetoacetic, linoleic, etc.
 - bile secretion and, 463
 - gastric secretion and, 437
 - reaction of urine and, 393, 394
 - free, of gastric contents, 438, 439
 - total, of gastric contents, 438, 439
- Acid-base balance of blood, 104 et seq.
 - at high altitudes, 362
 - in epilepsy, 903
 - in tetany, 701, 702
 - gastric secretion and, 426
 - role of kidney in regulation of, 391
- Acidophil cells of pituitary, 722, 725
- Acidophil tumor of pituitary, 735
- Acid metaprotein, 426
- Acidosis, 106, 108
 - dyspnea in, 354, 356, 357
 - in diabetes, 574
 - in renal disease, 410
 - in starvation, 607
- A-C interval of venous pulse, 189
- Acrocyanosis, 255
- Acrodynia, 644
- Acromegaly, 736, 737
 - milk secretion in, 766
 - production of by growth hormone, 724, 725
 - specific dynamic action and, 556
- Acromicria, 739
- Action currents, from auditory nerve, 1038, 1039
 - from brain, see Electroencephalogram
 - from cochlea, 1038
 - in heart, see Electrocardiogram
 - in nerve, 788 et seq.
 - in olfactory pathway, 1057
 - in optic nerve, 974, 975
 - in retina, 971, 973, 974
- Action potentials, see Action currents
- Acyl phosphates, 328
- Adaptation of receptors, 806, 807, 808
 - of retina to changes in illumination, 967
 - of sinus nerve, 243
 - olfactory, 1055
- Addisonian anemia, see Pernicious anemia
- Addison's disease, 697, 698
 - basal metabolism in, 536
 - denervation of adrenals for, 691
- Adenase, 566
- Adenine, 564, 565, 566
- Adenomatous goiter, 672
- Adenosine, 253, 280, 281, 566
 - action of in angina pectoris, 281
 - on coronary circulation, 280
 - production of heart block in guinea pig by, 253
- Adenosine diphosphate, 613, 615
- Adenosinetriphosphatase, 335, 616
- Adenosinetriphosphate formation of energy-rich bonds in, 334
 - in muscular contraction, 335, 613, 614, 615, 616
 - utilization of phosphate bond energy, 334
- Adenylic acid, 253, 564, 565, 616
- Adiadochokinesis, 930
- Adipose tissue, human, caloric value of, 610
- A D P, see Adenosinediphosphate
- Adrenal cortex, 692 et seq.
 - action of on sodium absorption from renal tubule, 385
 - atrophy of after hypophysectomy, 726, 728
 - carbohydrate metabolism and, 586, 587, 695

- Adrenal cortex—*Cont'd.*
 development and structure of, 684
 excision of, 692 et seq.
 hyperfunction of, 698, 699
 hypertrophy of by corticotropin, 684
 hypertrophy of in pituitary basophilism, 737
 insufficiency of, 693 et seq.
 ketogenic effect of, 605
 lipids of, 684
 milk secretion and, 766, 767
 obesity and, 609
 pantothenic acid deficiency and, 645
 principles of, 693 et seq.
 renal hypertension and, 132
 sex functions and, 695
 tuberculous disease of, 697
 tumour of, 698, 699
 vitamin C in, 647
- Adrenalectomy, effect of on milk secretion, 767
 on "vagal escape", 206
 survival after, 692, 693
- Adrenal gland, see also Adrenal cortex, Adrenal medulla
 atrophy of after hypophysectomy, 684
 denervation of, 691
 excision of, 692, 693
 functional relationship with thyroid, 672
 hypertension and, 128, 132, 135, 727
- Adrenaline, 685 et seq.
 action of on basal metabolism, 536
 on bile secretion, 463
 on body temperature, 631
 on carbohydrate metabolism, 586
 on cardiac output, 227
 on cerebral vessels, 290, 292
 on coagulation time, 92
 on coronary vessels, 280
 on fatigue of muscle, 825, 826
 on hepatic veins, 286
 on intestinal motility, 501
 on intestine after denervation, 947
 on motility of gallbladder, 475
 on pupil, 1014
 on salivary glands, 422
 on uterus, 731
 depressor action of, 687, 691
 liberation of and acetylcholine, 948
 hypothalamus and, 883
 in exercise, 211
 pain and, 240
 production of from tyrosine, 697
 secretion of, 689, 690
 sympathetic system and, 735, 945
 ventricular fibrillation and, 198
- Adrenaline-like substances, 211, 688
- Adrenal insufficiency, 692-698
